ABSTRACT – Recent work at Vinča-Belo Brdo has combined a total of more than 200 radiocarbon dates with an array of other information to construct much more precise narratives for the structural history of the site and the cultural materials recovered from it. In this paper, we present the results of a recent attempt to construct formal models for the chronology of the wider Vinča potscape, so that we can place our now detailed understanding of changes at Belo Brdo within their contemporary contexts. We present our methodology for assessing the potential of the existing corpus of more than 600 radiocarbon dates for refining the chronology of the five phases of Vinča ceramics proposed by Milojčić across their spatial ranges, including a total of 490 of them in a series of Bayesian chronological models. Then we outline our main results for the development of Vinča pottery. Finally, we discuss some of the major implications for our understanding of the source, character and tempo of material change.

IZVLEČEK – Nedavne raziskave najdišča Vinča-Belo Brdo združujejo več kot 200 radiokarbonskih datumov z zbirko drugih podatkov z namenom ustvariti bolj natančne zgodbe o strukturni zgodovini najdišč in o izkopanem kulturnem materialu. V tem članku predstavljamo rezultate nedavnih poskusov oblikovanja formalnih modelov za kronologijo na širšem območju kulture Vinča, da lahko umestimo zgodbe o razvoju spremen v kulturi na Belem Brdu v njihove sočasne kontekste. Predstavljamo tudi našo metodologijo za ocenjevanje potenciala obstoječega korpusa radiokarbonskih datumov, ki bi vplivala na kronologijo petih faz Vinčanske keramike, kot jih je postavil Milojčić, v njihovih prostorskih omejitvah, vključno s skupaj 490 datumov v seriji bayesovega kronološkega modeliranja. Na koncu razpravljamo o nekaterih glavnih posledicah naše razumevanja vira, značilnosti in hitrosti spremen v materialni kulturi.

The significance of the Vinča culture for the development of the Neolithic in SE Europe

The Vinča culture belongs to the latter part of the sixth millennium cal BC and the first half of the fifth millennium cal BC (Chapman 1981; Marković 1984; Borić 2009; Porčić 2011; Orton 2012). Its broad distribution extends through the river valleys – the Danube, its tributaries and their catchments – of the northern and central Balkans, from southernmost Hungary and easternmost Croatia through Serbia down to Kosovo and parts of Macedonia, and from Croatia and Bosnia and Herzegovina eastwards as far as parts of Transylvania in Romania and western Bulgaria (Fig. 1). The phenomenon presents a series of significant changes in the character of Neolithic settlement and social relations (Garašanin 1979; Chapman 1981; Kaiser, Voytek 1983; Tringham, Krstić 1990a), following the initial establishment of Neolithic existence in the area of its distribution from the late seventh and early sixth millennium cal BC onwards (Whittle et al. 2002). These include changing materiality; the expansion of material networks; the spread, consolidation and diversification of settlement, involving increased sedentism in the form of large settlements and tells; the intensification of subsistence; the introduction of copper metallurgy; and the emergence of both larger communities and distinctive households within them (Chapman 1981; 2000; Kaiser, Voytek 1983; Tringham, Krstić 1990a; Trpićović, Milić 2009; Orton 2010; Orton et al. 2016). Important issues of settlement expansion, population increase, changes in production, a greater variety of sites including tells themselves, more permanence of occupation, the role of households and the nature of community have all been much discussed (see also Borić 2009; 2015; Borojević 2006; Chapman 1990; Crnobrnja et al. 2009; Lazarović 1979; Link 2006.93–6; Orton 2010; 2012; Porčić 2012; Schier 1995; Tasić 2011; Tringham et al. 1992; Trpićović 2011; Whittle 1996.105).

It has been clear since the first radiocarbon dates (see Chapman 1981) that these features developed over a timescale of several centuries. Explanations of the radical transformations which both the emergence and the demise of the Vinča culture brought have varied considerably, from migrations within the culture history framework (e.g., N. Tasić et al. 1990.32–33; cf. Hervella et al. 2015), to the increasing importance as time went on of individual households and competitive social relations (Tringham, Krstić 1990a; Chapman 2000). One widely shared view, within a culture-historical framework, has been of southern origins for both initiation of the Vinča culture and subsequent changes during its development (such as the claimed ‘shock of Vinča C’ (e.g., Garašanin 1951; 1979; G. Lazarović 2000; Suciu 2009)). So the Vinča phenomenon is central to our understanding of social and cultural change in Neolithic southeast Europe, and also in surrounding areas. Despite the host of interpretations and chronological schemes produced, however, it remains the case that the calendar dating of Vinča culture changes – which principally boil down to changes in pottery – has not so far been rigorously or widely established, though important earlier efforts in that direction should be noted (Borić 2009; 2015; Orton 2012; Schier 1995; 1996; 2000; 2014).

Periodisation schemes for Vinča ceramics: a brief historiography

Distinctive material culture, including modelled face-like lids, figurines and copper artefacts but predomi-
A Vinča potscape: formal chronological models for the use and development of Vinča ceramics in south-east Europe

nantly the ubiquitous, abundant and high-quality, dark-burnished pottery, has been the basis for classic periodisations of Vinča material (see Tasić et al. 2016a; Fig. 2). That these in turn have been the spur for prolonged debate about the nature and source of origins and subsequent changes underlines their continuing importance. The practice of researchers has been to infer chronology from changing typological phases of ceramics, sometimes placing this on an absolute scale by reference to the available radiocarbon dates or by analogy with dated schemes from neighbouring areas. This approach assumes that two typologically identical assemblages are synchronous, no matter their geographical location. Variation through time and variation through space are thus conflated by this approach, which has been the source of much confusion, controversy and debate.

Gordon Childe (1929.27–32; cf. Menghin 1931) had enough data to distinguish only two phases (Vinča I and II). This was based mainly on Vinča-Belo Brdo, since this provided the most abundant material. The next, more developed periodisation of Vinča-Belo Brdo was by Friedrich Holste (1939) based on the typology of pottery excavated and published by Mi- Iloje Vasić, and dividing the material into five phases labelled A–E, with phases A–D covering the Neolithic development of the site. Although redefined and remodelled by later authors, this basic structure continues to underpin most periodisations of Vinča material as a whole.

In 1943 and 1949 Vladimir Milojić proposed a further refinement, using exclusively the published material from Vasić’s Preistoriska Vinča I. He basically reproduced Holste’s scheme but added sub-phases B1 and B2. His phase B1 denotes a time when meanders still appear as a decorative motif and his phase B2 is the time of appearance of curvilinear motifs which were more visible in the following Vinča C phase. Milojić also identified a transitional C–D phase between 4.5–4 m, marking the transition to the last Neolithic phase at Belo Brdo (Milojić 1949a.266–267; see also a useful English summary in Milojić 1949b). He was also the first fully to incorporate other Late Neolithic sites from the central Balkans into his chronological system.

Milutin Garašanin (1951) was the first to make an inventory of the entire pottery collection from Vasić’s excavations at Belo Brdo. He systematised the ceramic material and divided it into two major phases, Vinča-Tordoš and Vinča-Pločnik, also drawing

![Fig. 2. Overview of alternative typological schemes for Vinča ceramics (after Schier 1996).](image)

1 Some of his descriptions reveal that he had in-depth first-hand knowledge of the finds.
on material from other sites in the wider Vinča distribution. He used the labels Tordoš and Pločnik to link his early and late phases of the Vinča sequence with the northernmost and southernmost sites known at the time. At first he sub-divided both his Vinča-Tordoš and Vinča-Pločnik phases, and later elaborated this division even further (Garašanin 1969; 1993). He also incorporated the views of Borislav Jovanović (1994) on the Gradac phase, which stands for a sudden and significant change in the pottery forms first attested at the southern Serbian site of Gradac2.

Overlapping with and following the work of Garašanin, other periodisations essentially also based on the typology of pottery, such as those by Dumitru Berciu (1961), Stojan Dimitrijević (1968; 1974) and Gheorghe Lazarovici (1979; 1981), considered various areas of the Vinča distribution. In his quite brief treatment, Berciu essentially followed the structure already established by Milojčić, using the A–D terminology and still therefore with ultimate reliance on Vinča-Belo Brdo; his subdivision of Vinča B differs slightly from that of Milojčić and he proposed a tripartite division of C. Vinča is correlated with other cultures of south-east Europe. His scheme principally covers Banat, Oltenia, Muntenia and Transylvania. He made some reference to available uncalibrated radiocarbon dates and suggested a relatively low absolute chronology (Berciu 1961.Fig. 1, Pl. I).

In turn, Dimitrijević concentrated on northern Serbia, Romanian Banat and Croatian Slavonia, primarily focusing on what was then called the Sopot-Lengyel culture, and using key sites like Bapska and Vinčo, but with consideration of relationships and correlations with its neighbours. In this, reference was still made to Vinča-Belo Brdo by depth, with variation in subdivisions of B, C and D; for the first time, Vinča D is subdivided into D1 and D2, beginning at a depth of 4.5m at Belo Brdo (Dimitrijević 1968.89, kronološka tabela). Subdivision of A followed in a later article (Dimitrijević 1974). No reference was made to radiocarbon dates, in a work completed in 1964 and a very low absolute chronology was proposed, underpinned by supposed Vinča links to Northern Greece (Dimitrijević 1968.121–122).

There followed further periodisation of the Neolithic ceramic sequence in the Banat of north-west Romania by Lazarovici (1979), using the stratigraphy of key sites such as Gornea and Parta, but yet again with reference to Vinča-Belo Brdo. The basic structure for the Vinča sequence remains familiar in outline, but A is now subdivided differently, C is simplified, a C–D phase is reinstated, and D is proposed as a single unit; transitions were also added, as A3 between A2 and B1, and B1/B2 and B2/C, equivalent to what were seen as hiatuses in the Belo Brdo sequence (G. Lazarovici 1979. Tab. 7, 76). While a range of other material is considered, it is the forms and decoration of the pottery which are described in most detail, phase by phase (G. Lazarovici 1979.105–139). Potential imports, from surrounding groups such as the Alföld Linearbandkeramik, Szatmár, Bükk and Petrești, are also noted (G. Lazarovici 1979.163–168). Detailed attention was given to small-scale geographical variation within the Banat, explicit distinction was made between relative and absolute chronology, and comparisons were made with much further afield, as far as Anatolia and Mesopotamia (G. Lazarovici 1979 Tabs. 17–18, 178–179). A late absolute chronology is proposed, with the Vinča sequence placed between the late fifth and later third millennia (G. Lazarovici 1979.Tabs. 17–18, 178–179). The origins of the Vinča culture, with differences to the preceding Starčevo-Cris complex, were seen as lying in a complex set of cultural and ethnic changes and fusions, affecting the Balkans as a whole (G. Lazarovici 1979.221).

Subsequently, a review of the Vinča culture across Romania, summarising chronological trends in Oltenia and Transylvania/Siebenbürgen as well as Banat, reinforced this scheme; the C–D phase was omitted on this occasion (G. Lazarovici 1981.Beilage 1). There is still no reference to radiocarbon dating, and the chronological table lacks any absolute timescale. Famously, Vinča C was later characterised as a ‘shock’, involving migration from areas to the south (G. Lazarovici 1987). Further detail and refinement for Vinča C in the Banat were provided by Florin Drașovean (1994; 1996; Drașovean et al. 1996).

Other reviews of the Romanian Neolithic have been published subsequently (e.g., Mantu 2000; C.-M. Lazarovici 2006; Suciu 2011). By the time of these papers, calibrated radiocarbon dates, even if rela-

---

2 Unfortunately, Garašanin (1979.152) misunderstood Milojčić's subdivision, maintaining that, according to the latter, the transition between Vinča B2 and C would occur around a depth of 5m at Belo Brdo, instead of at 6m as Milojčić had clearly stated. This led to several decades of mismatch between the two typological systems, since researchers more familiar with the Garašanin scheme consistently 'translated' the phase Vinča-Pločnik I back into the Milojčić scheme as 'Vinča B2–C' instead of correctly 'Vinča C'. We have been aware of this issue when interpreting the published ceramic phasing of dated sites in the analyses below.
A Vinča potscape: formal chronological models for the use and development of Vinča ceramics in south-east Europe

Relatively few in number, were incorporated into chronological periodisations. It is worth noting that terms such as ‘wave’, ‘colonisation’ and ‘penetration’ are frequently used with reference to the Vinča culture; for example, “Vinča culture is part of the second great wave of southern origin” (Suciu 2011:75). On the basis of available radiocarbon dates, geographical variation in the effect of ‘Vinča C type communities’ is seen, with contrasts between Transylvania on the one hand and Banat and Oltenia on the other; in Transylvania, these are seen as determining the appearance of the Copper Age, whereas in Banat and Oltenia, the beginning of the Copper Age is related to new migrations due to the Tiszapolgár and Sâlcuța cultures (C.-M. Lazarovici 2006:277). Recently, Drașovean (2014) has argued that the beginning of the Copper Age in Banat and Transylvania is tied to the emergence of Foeni-Petrești communities.

Hermann Parzinger (1993) quantified the varying occurrence of selective decorative motifs and forms by depth through the Belo Brdo tell. Following the common perception at that time, he did not assign chronological significance to the sequence of material from the relative depths in the tell, but instead gave more weight to what he considered closed assemblages, like the few house inventories recognised by Vasić (Parzinger 1993:60–63). However, this resulted in a rather small number of, arguably, unrepresentative assemblages being used in his analysis. Parzinger incorporated this in a comparative, typologically based scheme (deliberately without reference to radiocarbon dates: Parzinger 1993:273) of successive cultural horizons, which covers the wider west Balkan region, and far beyond. At Belo Brdo itself he identified a series of Phases (I–VI), and over much wider areas a succession of horizons (i, 5a and 6–8 running parallel to the Belo Brdo sequence; Fig. 2).

The A–D division was endorsed by John Chapman (1981) for pragmatic reasons, to enable comparison within the wider Vinča culture. In his work, phases A–C denoted early Vinča and phase D late Vinča. Going beyond Vinča-Belo Brdo, and drawing on

![Fig. 3. Selected pot forms by depth at Vinča-Belo Brdo (after Milojević 1943).](image)
the then available radiocarbon dates (Chapman 1981: Fig. 14), he sketched sequences for five regions: Serbia and Macedonia, the Vojvodina, north Bosnia, Oltenia and Transylvania (Chapman 1981: 22–31). Taking just the example of decorative motifs on ‘early Vinča’ pottery, he was able to show significant regional variation (Chapman 1981: Fig. 11).

The scheme developed by Wolf-ram Schier consists of eight main phases and several sub-phases, and covers the sequence from the beginning of the Vinča occupation on the Belo Brdo tell to 4m from its top (Schier 1995; 1996; 2000). This was based on detailed analyses of changes in the form and decoration in a sample of about 2500 mostly unpublished vessel fragments (mainly bowls) recorded by relative depth, and its chronological credibility was tested by correspondence analysis. Schier also compared the newly defined phases with data from several other sites and concluded that the proposed division is valid at least for the ‘core’ area of the Vinča distribution, within a radius of some 100km of Vinča-Belo Brdo itself, in the middle Morava, Šumadija and the Banat (Schier 1995: 251–293; 1996: 147).

Finally, since the appearance of Schier’s chronology, Garašanin (2000) has refined his chronological system even further, consistent with Schier’s results. Additional subdivisions have been added, including Vinča-Tordoš IIb 1–3.

Regional differences, imports, imitation and influence: issues of variability

The brief review above documents how the culture concept has persisted, perhaps largely for reasons of convenience. But it is also perfectly clear that many specialists have sought both intra- and inter-regional variation within the Vinča ‘culture’ (e.g., Garašanin 1979; G. Lazarovici 1979; Chapman 1981). The notion of a Vinča core radiating around Vinča-Belo Brdo has been proposed (Schier 1995), though this may not necessarily be accepted from the perspective of other areas (Leković 1990; Makkay 1990; Jovanović 1994). There is clear recogni-

Fig. 4. Szederkény-Kukoricadúló, Grave 2484 accompanied by a Vinča A1 (Schier 1995) bowl (after Jakucs et al. 2016).

tion, even within the culture-historical framework, that the affiliation or allegiance of particular regions may shift through time; cultural boundaries were not immutable or permanently fixed. Actual imports from neighbouring or surrounding regions have also been claimed, as noted above (G. Lazarovici 1979), and other potential examples were given by Cornelia-Magda Mantu (2000:80) and Florin Drașovean (1994; 1996), among others. Complex, wide-ranging interactions and fusions have been envisaged. So, at various levels, many scholars have in practice broken down a monolithic Vinča culture into a more varied and nuanced network. Yet in many accounts there is also a reversion to single explanations, especially when it comes to moments of key transition, in terms of emergence, possible rupture and endings, and the dominant threads linking these are the claimed importance of areas to the south, in the southern Balkans, northern Greece and beyond, and inferred migrations.

Given developments in aDNA studies (e.g., Brandt et al. 2013; Szécsényi-Nagy et al. 2015; cf. D. Hofmann 2015), we have to deal with population changes and infiltrations (and see again Hervella et al. 2015; and further discussion below). But what is missing from the wider field of Vinča culture studies is a more reflective sense of possible diversity and variability. The task then becomes to attempt to unpick the complex cultural history of interaction, innovation, imitation, influence, copying and import-
ing, not excluding the possibility of population movement and replacement but equally not assuming \textit{a priori} that those should be the default explanations for change and variation. This paper proceeds on this basis, using pottery as its principal evidence. Ultimately, the whole range of Vinča material and practices should be the goal.

**Pottery as proxy dating: absolute chronology and typochronology**

Finally, by way of introduction, it is important to underline the difference between relative chronology, or sequence provided by a combination of typology (and on occasion seriation based on correspondence analysis: Schier 1995; 2000) and site stratigraphy, and absolute dating, based on formal modeling of calibrated radiocarbon dates on short-lived samples of known taphonomy, that are robustly associated with the archaeological contexts or diagnostic assemblages which they are used to date. Past generations of researchers, in the absence of large assemblages of high-quality radiocarbon dates and adequate statistical methodologies for their rigorous interpretation, have perforce attempted the synchronisation of relative sequences of pottery types based on typological considerations (perhaps with reference to the limited numbers of low-quality radiocarbon dates available to them). This form of ‘pseudo’ absolute chronology must be distinguished from what we propose here, which is the synchronisation of such sequences on the basis of robust statistical models of large numbers of radiocarbon dates that are directly associated with pottery which can be fitted within a common typological sequence. This approach builds upon the careful typological schemes of past research\(^3\), but in proper combination with scientific dating, adds absolute timescales to these sequences. Such timings, as we describe below, allow us to disentangle spatial from chronological variation in the use of these well established types.

**Aims of this paper: dating a potscape**

As we have seen, the Vinča culture has long been a familiar part of the culture-historical vocabulary used to frame, order, and interpret the Neolithic of south-east Europe. Many past notions derived from the use of the culture concept, however, including those of origins, identity and change, appear to have been based, in the end, largely or principally on the character and distributions of pottery styles, and the case of the Vinča complex is no exception. We are going to use the wealth of knowledge about Vinča pottery which has been built up over now a century and more of research as a key component in constructing a formally modelled chronology for the development of Vinča pottery across its wide distribution. If the landscape is what can be seen, and a taskscape what can be heard (Ingold 1993,162), a Vinča potscape could be defined as what could be held in the hands of the makers and users of the many ceramic assemblages across that distribution: borrowing Ingold on the taskspace (1993,158), “the entire ensemble ... in their mutual interlocking ... an array” of related forms. Harnessing, rather than casting aside, many of the strengths of past research on the Vinča phenomenon, we seek to discuss the many implications of our model for questions of the character and tempo of material change, and the nature of cultural variability. While we do not avoid the term, ‘the Vinča culture’, alternative terminology could help to recast many traditional debates (Porčić 2012,171; Borić 2015,189–195), and from here on we use other terms such as network to characterise the potscape under discussion.

In a major project, \textit{The Times of Their Lives} (see Acknowledgements), we have obtained substantial numbers of new radiocarbon dates and formally modelled the results in a Bayesian statistical framework for four sites with Vinča pottery: the tell of Vinča-Belo Brdo, in northern Serbia (Tasić et al. 2015; 2016a; 2016b), the tell of Uivar in western Romania (Drașovean et al. submitted; Schier et al. in preparation), and the flat settlements at Szederkény and Versend, in south-west Hungary (Jakucs et al. 2016; submitted). Encouraged by the coherent results from these sites, we were then interested to see if we could put these into the broader framework of the development of the Vinča network concentrating on the potscape of ceramic change. For this we have collected the published and other radiocarbon dates available to us in 2015. For our investigations at Vinča-Belo Brdo, we provided formal estimates for several of the available ceramic schemes (Tasić et al. 2016a.Figs. 22–24, Tabs. 8–9; and see

\(^3\) But we note the lack of rigorous, quantitative typo-chronological studies on statistically viable samples of Vinča ceramics, and the lack of representative analysis and full publication of excavated assemblages. These deficiencies in the analyses and publication of Vinča assemblages have been the major obstacle in the construction of the chronological models presented below rather than any lack of good-quality radiocarbon dates.
Fig. 2), but for this paper we have used, for the sake of simplicity and wide applicability, the A–D scheme of Milojčić (1943; 1949a). Specifically, we aimed to:

- relate our models for Vinča-Belo Brdo, Uivar, Szederkény and Versend to the wider pattern of ceramic change, formally modelled within the A–D scheme for the Vinča culture;
- examine critically the temporal and geographical coherence of the A–D scheme;
- identify temporal and geographical variation in the adoption, maintenance and abandonment of ceramic styles within the A–D scheme;
- and by these means investigate the character and tempo of cultural change.

**Scientific dating and Bayesian chronological modelling for Vinča ceramics**

The first radiocarbon dates for Vinča ceramics were very much in the tradition of their time — one or two samples of charred material from a given site. Only a handful of sites had three to six dates. Vinča-Belo Brdo itself was fortunate to obtain two measurements on charred grain samples (GrN-1537 and GrN-1546; Vogel, Waterbolk 1963:183–184), and one measurement on a sample of unidentified charcoal (GrN-1555; Todorović, Germanović 1961:71).

At the beginning of the 1980s, Chapman (1981:17–31) was able to gather details of 36 radiocarbon dates from 16 sites from which Vinča pottery had been recovered, and used these uncalibrated radiocarbon dates in comparison with local stratigraphic sequences. He reached three major conclusions: that the duration of phases A–C was comparable to the duration of the entire D phase; that the final centuries of the Vinča culture were not represented at the type-site; and that the different rates of development in the various regions prevent Vinča Belo Brdo from being used as a ‘type-site’ for the development of the Vinča culture as a whole.

In the 1990s, Schier (1996:Tab. 1) obtained a series of 14 conventional radiocarbon dates on worked antlers and large animal bones that had been recovered by Vasić at Belo Brdo and recorded by depth. These derive from the lower and middle part of the tell (4.1–9.3m) covered by his seriation of a sample of the surviving pottery assemblage. Using these results and the first series of dates produced in Groningen, Schier (1996:Figs. 11–12) produced the first Bayesian chronological model for Vinča-Belo Brdo, combining the radiocarbon dates with the depths through the tell recorded on the samples.

At the same time Roland Gläser (1996) presented a review of 76 radiocarbon dates from 14 sites containing Vinča ceramics. He provided a Bayesian chronological model combining the site stratigraphy with the corpus of radiocarbon dates for Selevac (Gläser 1996:Fig. 5), but otherwise his analysis is based on simple calibrated radiocarbon dates and summed probability distributions of calibrated dates for selected sites, and site and ceramic phases. He suggested that the Vinča culture spanned the period from c. 5200 cal BC to c. 4500 cal BC.

Dušan Borić (2009) mustered a total of 155 radiocarbon dates from 27 sites associated with Vinča pottery, including 40 new AMS measurements on short-life, single-entity samples from seven sites. Bayesian models were presented for six sites: Belo Brdo, Rudna Glava, Belovode, Pločnik, Gomolava and Divostin II. This analysis suggested that the culture dated from 5400–5300 cal BC to 4650–4600 cal BC. Contrary to Chapman, Borić argued (2009: 234) for an approximately similar duration of each phase (A to D) of 200±50 years. More recently, a set of 26 new AMS dates on animal bone from Gomolava, Opovo and Petnica have been published and Bayesian models constructed (Orton 2012). These new dates generally fit the chronological framework suggested by Borić.

**The chronological framework and approach**

It is now time not only to compare these new site chronologies with each other, but also to set them within the wider framework of other dated sites that formed part of the Vinča network. We consider a corpus of 564 radiocarbon dates that have been published as relating to Vinča pottery (Tab. 1)\(^4\). Full details of these measurements are provided in Table 2 where we have gathered information from diverse sources or when measurements are published for the first time. Where full details of measurements have already been published (e.g., Borić 2009) references to sources used for each site are provided in Table 1.

Chronological modelling has been undertaken using the program OxCal v4.2 (Bronk Ramsey 2009; Bronk Ramsey 2015). Additionally, there are 34 radiocarbon dates from the latest levels of Vinča-Belo Brdo in Sector II (Tasić et al. 2015), 101 from the recently excavated deep sounding (Tasić et al. 2016b), and two from the 2011 profile that are not considered here.
Ramsey, Lee 2013) and the calibration dataset of Reimer et alii (2013). The algorithms used in the models are defined exactly either by the brackets and OxCal keywords on the left-hand side of the figures or by the CQ2 code provided as supplementary information (http://c14.arch.ox.ac.uk/). In the figures, the outputs from the models, the posterior density estimates, are shown in black, and the unconstrained calibrated radiocarbon dates are shown in outline; dates on samples of charred plant remains that may have an old-wood offset are shown in grey; the parameter names of distributions that have been excluded from the modelling are followed by ‘?’. Some distributions do not relate to single radiocarbon dates. These other distributions correspond to aspects of the model. For example, the distribution ‘start Szederkény’ (Fig. 5) is the posterior density estimate for the time when the settlement at Szederkény was established. In the text and tables, the Highest Posterior Density intervals of the posterior density estimates are given in italics. Calibrated date ranges given in normal type have been calculated using IntCal13 and the probability method (Stuiver, Reimer 1993), and do not derive from the chronological models described. All ranges have been rounded outwards to five years.

For each measurement, we examine the character of the dated material and its association with Vinča ceramics. Given the absence of an agreed typological scheme across the region, assemblages have been allocated to Milojčić’s (1943; 1949a) scheme: A, B1, B2 (incorporating what was later called the Gradac phase), C (incorporating Milojčić’s (1949a; 1949b) phase C–D), and D (incorporating all proposed subdivisions) (Fig. 3). Where site stratigraphy is available, this is used in a Bayesian model to constrain the calibration of the radiocarbon dates. In some cases the available published information is not sufficient to demonstrate a robust association between the dated samples and a ceramic phase(s) (these results are reported in footnotes).

Ideally, we wish to include in our models only radiocarbon dates on short-life samples that are directly associated with typologically diagnostic assemblages of the relevant pottery. Dates on articulated animal bones from closed ceramic assemblages in pits, for example, are ideal (for a demonstration of the potential of this approach see Denaire et al. in press). Unfortunately, the samples submitted for dating by past researchers, the published typological and stratigraphic information, and the reporting of the radiocarbon measurements and their associated details (Bayliss 2015) are frequently less than ideal. In these circumstances, we have been forced to make pragmatic judgements about the information available to us.

We have only included radiocarbon dates in our study that are published as having a clear association with Vinča ceramics that have been assigned to various typological schemes (cf. Fig. 2), which we have converted to the Milojčić (1943) scheme. This means that sites often have more radiocarbon dates than have been used in the modelling, but these are either associated with activity of other periods or do not have explicit associations with diagnostic Vinča material. In many cases it has been impossible for us to judge the validity of the published ceramic association, as sites are not yet published in detail. Sometimes associations cannot be made at the feature or structure level, but rather an entire site is categorised as only containing material of a certain phase. It should be noted that the association between cultural material and the radiocarbon sam-

---

**Fig. 5.** Probability distributions of key parameters from Szederkény-Kukurica-dűlő, derived from the model defined by Jakuc et al. (2016.Fig. 10).
ple is critical to avoid circular arguments (by which a site is assigned to particular ceramic phase on the basis of the calibrated radiocarbon dates rather than the typological characteristics of the pottery present).

This legacy dataset is inevitably of variable quality. Although over 70% of measurements have been made by AMS, short-life, single-entity samples that can be confidently associated with the use of the feature from which the sample derived constitute less than a quarter of dates (and 80% of those derive from just two sites, Szederkény and Versend). Over 20% of samples were of unidentified charcoal (or of charcoal from long-lived species such as oak and elm) and so may incorporate an old-wood offset. Other samples consist of disarticulated animal bones or single carbonised cereal grains, where it is not known whether the dated material derived from particular concentrations. Such materials might well be residual (older than their contexts) or intrusive (younger than their contexts).

We have attempted to distil reliable chronology from this body of data, by incorporating each result into the model in a way that is appropriate for the dated material.

- Samples of human bone from graves, articulated animal bone groups, and short-lived charred plant remains (including short-life charcoal) from fired features such as hearths or large concentrations, such as coherent dumps in pits, have been incorporated into the models as short-life material likely to be contemporary with the archaeological activity of interest (n = 134).

- Disarticulated animal bones and short-lived charred plant material from houses or pits have also been included fully in the models, although we consider the archaeological association in this case to be less reliable (n = 244); in a number of cases the dates on these samples are clearly much earlier than related dates (usually having a poor individual index of agreement in the model) and so they have been modelled as residual termini post quos (n = 43), and in a few cases they are clearly intrusive (n = 8).

- Samples of unidentified charcoal (or charcoal from long-lived species) have been incorporated into the models as termini post quos (n = 115), except for a few which are statistically consistent with results on short-life materials from the same context (n = 5).

- Five results from Uivar have been excluded from the model for that site for technical reasons (Schier et al. forthcoming).

In total, therefore, our models include 490 radiocarbon measurements (with a further 66 not included in the analysis either because there is a significant possibility that the measurements are inaccurate, or because we think the dated material was intrusive, or because the association with the Vinča ceramics is unclear). A total of 134 measurements on short-lived samples firmly associated with the dated context are included fully in the models (27%); a further 193 measurements on short-life material that can be associated with the dated context less reliably have also been included fully in the modelling (40%), with another 43 such samples modelled as termini post quos as the dated material was probably residual (9%); and 120 measurements on charcoal samples of uncertain maturity are included in the models as termini post quos (24%). Our analysis suggests that overall there is approximately a 25% chance that a disarticulated animal bone, or a short-life charred plant from a deposit with which it is not functionally related, is residual or intrusive. This demonstrates the need to date articulating bone groups or single fragments of short-lived charred plant material from primary deposits (Bayliss et al. 2016).

This analysis provides quantitative date estimates for Milojčić’s (1943) ceramic phase boundaries at different sites that are independent of any synchronisation between alternative typological schemes. In some cases the character of the dated material means that samples can only provide termini post quos for particular ceramic phases, or can only be allocated to a range of ceramic phases. We start by considering the chronologies and ceramic associations of particular sites, and construct chronological models for sites which have more than three radiocarbon dates on short-lived material with robust ceramic associations. We then construct a series of models for the chronology of each of Milojčić’s ceramic phases, utilising posterior distributions from the site-based models as inputs for these models where appropriate and calibrated radiocarbon dates where not. This ensures that sites which have many radiocarbon dates (e.g., Uivar or Belo Brdo which between them have almost half of the radiocarbon measurements considered in this review) do not disproportionately affect the analysis.
The Vinča potscape

We discuss the dated sites from west to east, following the Danube downstream and examining sites in the catchments of its tributaries as these join the river (Fig. 1).

The Danube upstream of the Tisza

A linear strip 1.7km long, comprising 12.5ha, was investigated at Szederkény-Kukorica-dülő between 2005 and 2008. The site lies approx. 20km west of the current course of the Danube in south-eastern Transdanubia, Hungary. A total of 66 longhouses, orientated NE-SW and broadly conforming to the longhouse architecture which is generally perceived as a hallmark of the central European Linearbandkeramik (LBK), and 50 crouched inhumations were recovered. Most of the graves are unfurnished, although some were accompanied by Vinča ceramics (Fig. 4). Vinča pottery, from Schier’s (1996) A1–A3 phases, was recovered from settlement features (Jakucs, Voicsek 2015). This material can be related to Milojčić phase A used in this study.

Forty-one radiocarbon measurements are available from this site (Jakucs et al. 2016.Tab. 1), of which 19 are from features containing diagnostic Vinča A ceramics. These dominated the assemblages from the eastern and central areas of the site (the western part contained mainly Ražšte-type pottery). Jánoš Jakucs et alii (2016.Fig. 11) present a model for the chronology of Szederkény, which is summarised in Figure 5. This estimates that Vinča A ceramics appeared here in 5360–5315 cal BC (95% probability; start Szederkény; Fig. 5), probably in 5340–5315 cal BC (68% probability), and ceased to be used in 5230–5175 cal BC (95% probability; last Szederkény eastern; Fig. 5), probably in 5215–5190 cal BC (68% probability).

The site of Versend-Gilencsa lies in southern Hungary, approx. 2km east of Szederkény-Kukorica-dülő (Jakucs et al. submitted). A linear strip totalling 2.24ha was excavated along the planned line of the motorway, divided by the course of the Versend stream. Features of the Neolithic settlement could be detected on the floodplains of the eastern and western side of the watercourse.

On the eastern side, unambiguous traces of 21 longhouses orientated NE-SW could be identified. These were arranged in rows, and each was flanked by longitudinal pits containing mixed assemblages of early LBK and Vinča A ceramics. The density of archaeological features was higher on the western side, where the extensive traces of the Neolithic settlement were heavily destroyed by later activity. The houses were consequently much less identifiable.

Sixty-eight radiocarbon measurements are available from this site (Jakucs et al. submitted.Figs. 5–6). Jakucs et alii (submitted.Figs. 5–6) present a model for the chronology of Versend, which is summarised in Figure 6. This estimates that the settlement began in 5305–5280 cal BC (2% probability; start Versend settlement; Fig. 6) or 5255–5210 cal BC (93% probability), probably in 5235–5215 cal BC (68% probability), and ceased to be used in 5220–5180 cal BC (93% probability; end Versend settlement; Fig. 6) or 5150–5115 cal BC (2% probability), probably in 5210–5195 cal BC (68% probability).

Several occupation horizons that include assemblages of Vinča pottery have been recovered from the tell settlement at Bapska, eastern Croatia, in 13 campaigns of excavation between 1911 and the present (Burić, Težak-Gregl 2009; Burić 2011). Two radiocarbon measurements are available from the 1964 trench; one from the foundation of House 2–A is associated with an assemblage described by Dimitrijević (1968,92) as Vinča D1 and equated by him with Milojčić’s phase C–D. This dating, being on charcoal from a potentially long-lived species, thus provides a terminus post quem of 4850–4845 cal BC (Bln-348; 95% probability) or 4780–4780 cal BC (68% probability) for the end of Milojčić’s phase C at Bapska 5. A further series of radiocarbon measurements have recently been obtained on short-lived material associated with Houses 1 and 2 from renewed excavations (Burić, Težak-Gregl 2009; Burić 2015). These appear to be associated with Vinča C or Vinča D ceramics, and can be modelled as spanning 4645–4495 cal BC (95% probability; start Bapska C/D; Fig. 7), probably 4580–4515 cal BC (68% probability), and 4550–4420 cal BC (95% probability; end Bapska C/D; Fig. 7), probably 4535–4475 cal BC (68% probability).

Tisza and Mureş valleys

The site of Maroslele-Pana is located in south-eastern Hungary, on the right (northern) bank of the Maros (Mureş) river, northwest of the village of Maroslele, 5 A second sample from the 1964 excavations (Bln-346, 5955±80 BP, 5055–4665 cal BC (94% probability) or 4640–4615 cal BC (1% probability)) is associated with Sopot II pottery and is thus not included in this study.
close to the confluence of the Tisza and Maros rivers. The site was first excavated in 1963; four Neolithic features (pits 1–4) and five crouched burials were documented (Trogmayer 1964). The pottery from this early campaign represented the late phases of the early Neolithic Körös culture. In 2008 there were further excavations in advance of road construction. The excavation took place on a low ridge and covered 2.7ha. A total of 71 of the 231 excavated features can be dated to the Neolithic period (Paluch 2011). Five radiocarbon measurements were obtained on animal bone from separate pits (Tab. 2). The dated pits contained diagnostic early Vinča A1–A2 (Schier 1996) and early Alföld LBK style pottery, but also some fragments and altar pieces which showed clear resemblances to the pottery style of the late Körös culture. The Vinča A1–A2 elements are most frequent in pit 85, while the other dated pits contain more equal proportions of early Vinča and Alföld LBK style material. The mixed (Vinča and Alföld LBK with early Neolithic traits) assemblage of Maroslele-Pana in the Tisza-Maros confluence area (Paluch 2011) can be seen as a similar phenomenon to that observed at Versend-Gilencsa in southern Transdanubia and at Satchinez in northern Banat. The model for the dated activity from Maroslele-Pana has good overall agreement (Amodel: 106; Fig. 8) and suggests that the site was occupied between 5380–5220 cal BC (95% probability; Start Maroslele-Pana A; Fig. 8), probably in 5325–5250 cal BC (68% probability), and 5300–5095 cal BC (95% probability; End Maroslele-Pana A; Fig. 8), probably 5275–5195 cal BC (68% probability).

At Ószentiván (site 8) four measurements were taken on bulk charcoal from a pit containing Vinča A pottery that was investigated during rescue excavations in 1960 (Kohl, Quitta 1970). This material was identified as oak and elm charcoal, both species that can live to several hundred years, and so the combined result provides a terminus post quem for the pottery of 5305–5050 cal BC (95% probability; Ószentiván 8).

Fig. 6. Probability distributions of key parameters from the settlement at Versend-Gilencsa, derived from the model defined by Jakucs et alii (submitted.Figs. 5–6).

Fig. 7. Probability distributions of radiocarbon dates from Bapska. Each distribution represents the relative probability that an event occurs at a particular time. For each of the dates two distributions have been plotted: one in outline, which is the result of simple radiocarbon calibration, and a solid one, based on the chronological model used. Distributions other than those relating to particular samples correspond to aspects of the model. For example, the distribution ‘start Bapska D’ is the estimated date when Vinča D ceramics first appeared on the site. Measurements followed by a question mark and shown in outline have been excluded from the model for reasons explained in the text, and are simple calibrated dates (Stuiver, Reimer 1993). The large square brackets down the left-hand side along with the OxCal keywords define the overall model exactly.
or 5295–5245 cal BC (19% probability) or 5235–5200 cal BC (15% probability) or 5170–5075 cal BC (36% probability). A single sample of unidentified charcoal was dated from pit 1, recovered in later excavations at the same site (published as Tiszasi-get), which was also associated with Vinča A ceramics (Trogmayer 1980:298). This provides a *terminus post quem* for the assemblage of 5465–5445 cal BC (1% probability; Bln-1631) or 5380–5190 cal BC (78% probability) or 5185–5055 cal BC (16% probability), probably 5340–5205 cal BC (68% probability).

The site of At is located to the north-west of Vršac in south-eastern Banat, Serbia. The settlement was located on a sloping terrace on the north-west edge of Veliki rit, a marshy area drained in the mid-nineteenth century. Several seasons of rescue excavations revealed the existence of a multi-period prehistoric site, ranging from the Lower Palaeolithic to the Late Neolithic (Joanović, Prikic 1978). Renewed excavations in 2014–2015 revealed a structure of the Starčevo period, and cut features associated with Vinča C and Vinča D ceramics (Chu et al. 2016). Four radiocarbon dates are available from the Vinča layers, two from pit 1 and two from the infilling of the Starčevo structure. These place this activity between 6040–5960 cal BC (1% probability; Start At C/D; Fig. 9), or 5700–4660 cal BC (94% probability), probably in 5050–4720 cal BC (68% probability), and 4595–3510 cal BC (94% probability; End At C/D; Fig. 9), or 3180–3090 cal BC (1% probability), probably in 4535–4190 cal BC (68% probability). These estimates are extremely imprecise, with very long tails to the distributions, because there are currently few dates from this site.

Also in the vicinity of Vršac is the 100ha flat settlement of Potporanj, which has produced early Vinča pottery and the largest quantity of obsidian found within the Vinča network. Provenance studies of this material show that it came from the Hungarian and Slovakian Carpathian Mountains (Tripković, Milić 2009). Three radiocarbon dates are available from recent excavations of the site by Vršac Museum. MAMS-22667, a sample of unidentified charcoal that may have an old-wood offset, provides a *terminus post quem* of 5210–5000 cal BC (95% probability) or 5210–5160 cal BC (25% probability) or 5120–5105 cal BC (4% probability) or 5080–5005 cal BC (39% probability) for an assemblage of Vinča A ceramics in the earliest occupation level. MAMS-22666, also a sample of unidentified charcoal, provides a *terminus post quem* of 5215–5015 cal BC (95% probability) or 5210–5090 cal BC (51% probability) or 5085–5050 cal BC (17% probability) for the use of Vinča B2/C ceramics in the latest habitation level of the site. The third date, MAMS-22668, is on animal bone from a level associated with Vinča B2 pottery and dates this deposit to 5295–5240 cal BC (9% probability) or 5235–5190 cal BC (19% probability) or 5180–5060 cal BC (67% probability), probably 5220–5200 cal BC (13% probability) or 5170–5075 cal BC (55% probability).

![Fig. 8. Probability distributions of radiocarbon dates from Maroslele-Pana. The format is identical to that of Figure 7. The large square brackets down the left-hand side along with the OxCal keywords define the overall model exactly.](image-url)
probability), probably at 4795–4705 cal BC (68% probability).

The tell site of Uivar in the Romanian Banat was excavated between 1999 and 2009 by a Romanian-German team (Schier, Drașovean 2004; Schier 2008; Drașovean, Schier 2009; Schier 2016). It consists of a central tell settlement 4m high and covering some 3ha, which was surrounded by a series of substantial ditches, some accompanied by palisades. These enclose an area of some 12ha. A flat settlement occupied at least some of this, and may have succeeded occupation on the tell itself. A complete sequence through the tell was excavated in Trench 1. A recent programme of chronological modelling utilising a total of 182 radiocarbon measurements from the site formally estimates the chronology of this complex (Schier et al. forthcoming; Drașovean et al. submitted).

Only preliminary analyses of the pottery assemblages from the site have been undertaken so far. The lowest deposits in Trench 1 contained pottery predominantly in the Szakálhát tradition. The first Vinča-type sherds appear to be local imitations of Milojčić B1 (Schier 1995.phase B). They occur from the construction horizon of H3d in 5045–4990 cal BC (95% probability; build H3b; Fig. 10), probably in 5035–5000 cal BC (68% probability). The first sherds of Schier (1995) phase C1 (equivalent to late Milojčić B2, see Fig. 2) pottery appear in the construction horizon of H3c, which unfortunately could not be dated directly since the structure did not provide suitable samples. The date of its appearance can be estimated, however, since this must be between the construction of buildings H3d and H3b. This model is shown in Figure 10 and suggests that late Milojčić B2 (Schier 1995.phase C1) pottery first appeared in 5030–4930 cal BC (95% probability; start Milojčić B2 at Uivar), probably in 5010–4950 cal BC (68% probability). It becomes predominant on the site from the construction horizon H3b in 4985–4910 cal BC (95% probability; build H3b; Fig. 10), probably in 4960–4925 cal BC (68% probability). Milojčić C (Schier 1995.phase C2) pottery appears from the construction of the H3a horizon in 4920–4850 cal BC (95% probability; build H3a; Fig. 10), probably in 4905–4895 cal BC (8% probability) or 4890–4855 cal BC (60% probability). No sherds of Milojčić C-D (Schier 1995.phase D1) pottery have been recovered from Uivar, and so Milojčić C ceramics appear to have been current until the end of the Neolithic occupation of the tell in 4740–4600 cal BC (95% probability; end Uivar tell; Fig. 10), probably in 4725–4645 cal BC (68% probability).

Three samples of bone have been dated from the site at Tărtăria, Transylvania, Romania (Merlini 2011. 224; Merlini, Lazarovici 2008.156). One is from a partial female skeleton found disarticulated and mixed with animal bone in the pit which is thought to have contained the Tărtăria tablets, one from cleaning of the 1942–1943 section, and one from the base of pit B2. Merlini places the pottery from the pit containing the skeleton in the Vinča phase A2 or A3, although Lazarovici (2010.Fig 8) places the same assemblage in Vinča A3/B1; he also places the assemblage from pit B2 in this phase. We have interpreted these classifications to refer to an assemblage of Vinča B1 pottery, which contained surviving elements of Vinča A3.

The taphonomy of the dated material and its association with the recovered ceramics are problematic. The animal bone from the base of pit B2 probably provides a date for the associated Vinča B1 pottery (although, of course, it is always possible that a disarticulated bone is residual). This result calibrates to 5315–5000 cal BC (R-1655; 95% probability), probably to 5295–5250 cal BC (13% probability) or 5230–5195 cal BC (12% probability) or 5180–5065 cal BC (43% probability). The dated animal
bone from the section is effectively unstratified and cannot be securely associated with the pottery. Interpretation of the date on the female partial skeleton is more complicated, since there appears to be evidence that the body was exposed for a period of time before burial in the pit associated with the tablets. For this reason, in this study we have included this date as a terminus post quem for the use of the Vinča B1 ceramics from the pit. This is 5470–5200 cal BC (88% probability; R-1631) or 5165–5115 cal BC (4% probability) or 5110–5075 cal BC (3% probability), probably 5360–5215 cal BC (68% probability).7

The settlement at Miercurea Sibiului-Petriş, in the catchment of the upper Mureş valley, consisted of surface houses and pits (Luca et al. 2006). These appear to be associated with Vinča B ceramics. Four radiocarbon dates are available on short-lived materials from two pits and a house (Tab. 2)8. Pit 18 is stratigraphically earlier than pit 3 and house 11, although GrA-35127 from pit 18 appears to be on a residual cereal grain and so is incorporated in the model as a terminus post quem. This model has good overall agreement (Amodel: 79; Fig. 11), and suggests that Vinča B occupation here occurred between 5650–5025 cal BC (95% probability; Start Miercurea Sibiului-Petriş B), probably 5290–5095 cal BC (68% probability), and 5280–4590 cal BC (95% probability; End Miercurea Sibiului-Petriş B), probably 5170–4970 cal BC (68% probability)9.

---

7 This sample was an unidentified animal bone recovered from the cleaning of the section of the 1942/3 excavation and produced a date of 5310–4995 cal BC (95% probability; R-1630, 6200±65 BP), probably 5285–5270 cal BC (2% probability) or 5225–5050 cal BC (66% probability).

8 The radiocarbon dates raise the possibility that Milady of Tărtăria was curated for some time before her bones were buried in this pit. It is 83% probable that R-1631 is earlier than R-1655, probably by -115–375 years (95% probability; distribution not shown), probably 10–240 years (68% probability). The negative parts of these ranges reflect the possibility that her bones were freshly deposited.

9 A cattle rib that was dated from L3 house, square 6–8 (110–130cm), at Limba (GrN-28112, 6290±50 BP, 5375–5200 cal BC (88% probability) or 5170–5075 cal BC (7% probability), is from a house that was expected to be contemporary with the Criş IV ceramics within it (Biagi et al. 2005.49). The painted vessel has been attributed to Vinča A2 (Lazarovici 2009.184–185; 2010.115–116; 2014.16–18, Figs. 3, 5c), Vinča A2–A3 (Mazâre 2005.258, 288), or Starčevo-Criş IV (Dragoevery 2014,footnote 10). It appears to be a Lumea Noua import. The result is later than expected and has been reassigned to Vinča A3, although the publication does not provide evidence of an association with Vinča A3 ceramics. This result is therefore not included in the modelling presented here (Suciu 2009.37). Similarly, the association between the cattle tibia dated by GrN-28994 (5760±40 BP, 4710–4515 cal BC (95% probability) and the, probably earlier Vinča ceramics, recovered from Cauce Cave is unclear and this result is also not included in this analysis (Suciu 2009.67–9, Fig. 82, Annex 1).

---

This page contains a figure (Fig. 10) titled "Probability distributions of key parameters relating to the use of Vinča ceramics at Uivar. The format is identical to that of Figure 7. The large square brackets down the left-hand side along with the OxCal keywords define the overall model exactly (key parameters have been imported from the model defined by Schier et alii forthcoming.Figs. 6.9, 6.12–6.22)."
Sava valley and tributaries

The site of Lupljanica, with Vinča pottery, is located in the valley of the Bosna River, one of the main tributaries of the Sava in central Bosnia. A single sample of unidentified charcoal was dated from the lowest level of a house structure, 1.3m below the surface (Breunig 1987.107; Crane, Griffin 1972.190–191), and provides a terminus post quem of 4910–3985 cal BC (M-2455; 95% probability), probably 4705–4255 cal BC (68% probability) for the end of Vinča D.

The Neolithic tell at Gornja Tuzla is located on the slopes of Mt. Majevica in the upper part of the Jala river catchment. It was discovered in 1949 and is estimated to be between 12 and 15ha in size. Excavations were undertaken over four seasons between 1955 and 1958 (Čović 1961.79–139). Five radiocarbon measurements associated with Vinča period activity have been published, but only two have robust ceramic associations. These are measurements on unidentified charcoal found in association with Vinča C pottery that provide termini post quos for this pottery of 4535–4330 cal BC (GrN-1974; 95% probability) or 4460–4355 cal BC (68% probability) and of 4780–4355 cal BC (Bln-349; 95% probability) or 4685–4455 cal BC (68% probability).

The multi-period tell at Gomolava is in Vojvodina, Serbia, on the east bank of the river Sava. It was first detected in 1898, and small-scale excavations were undertaken in 1904–1908. The first systematic excavations took place between 1953 and 1985, with approximately half a hectare investigated (Girić 1988.13; Brukner 1980; 1988). This yielded a number of prehistoric occupation horizons ranging from the late Neolithic to late Iron Age. However, the site is best known for its late Vinča necropolis (Borić 1996; Jovanović 2015), one of only very few discovered thus far in the Balkans.

Fifteen samples are on unidentified charcoal and may have contained material with an old-wood offset; the other 17 samples are on short-lived materials (two bulk samples of carbonised cereal grain, four human burials, and 11 animal bones; Waterbolk 1988.Beilage 1; Orton 2012.Tab. 2; Borić 2009.Tab. 5).

A model for the dated Vinča activity at Gomolava has good overall agreement between the radiocarbon dates and the stratigraphic information (Amode: 80; Fig. 12), only if three dates that fall in the early Bronze Age are excluded as outliers (all considered to be intrusive from later phases of activity: GrN-7373, GrN-7375 and OxA-21132).

The model presented in Fig. 12 suggests that Vinča C started at Gomolava in 5005–4845 cal BC (95% probability; Start Gomolava C; Fig. 12), probably in 4955–4875 cal BC (68% probability); the boundary between phases C and D occurred in 4810–4720 cal BC (95% probability; Gomolava C/D; Fig. 12), probably in 4790–4735 cal BC (68% probability); and

![Fig. 11. Probability distributions of radiocarbon dates from Miercurea Sibiului-Petriș. The format is identical to that of Figure 7. The large square brackets down the left-hand side along with the OxCal keywords define the overall model exactly.](image)

10 Three further measurements have been obtained from more recent excavations at Gornja Tuzla (Vander Linden et al. 2014). OxA-23297 (6165±34 BP, 5220–5015 cal BC (95% probability)) on a large mammal bone from layer 15 does not appear to be securely associated with a diagnostic ceramic assemblage. Two further statistically consistent measurements (OxA-23298, 5827±33 BP, 4785–4590 cal BC (95% probability) and OxA-23299, 5741±33 BP, 4690–4500 cal BC (95% probability); T' = 3.4; v = 1; T(5%) = 3.8) were obtained on different species of animal bone (Bos taurus and Cervus elaphus) from layer 8. These samples also have no known direct ceramic associations.
phase D ended here in 4670–4500 cal BC (95% probability; End Gomolava D; Fig. 12), probably in 4635–4550 cal BC (68% probability).

The Neolithic settlement at Petnica is located in the Kolubara valley area in western Serbia, on a slope running up to a north-facing cliff. A cave in this cliff was also occupied in this period. The site has been excavated on several occasions, yielding three late Neolithic occupation phases and several Vinča-period wattle and daub structures (Starović 1993).

Seven radiocarbon dates have been obtained on animal bone samples from occupation features at Petnica (Borić 2009. Tab. 6; Orton 2012. Tab. 2). The model for the dated activity at Petnica has good over-
all agreement (Amodel: 94; Fig. 13), if we interpret Pit 3 as being cut from above the level of House 3 and if we interpret the animal bone from House 2 as residual. We follow the ceramic phasing for Petnica published by David Orton (2012).

This model suggests that phase B2 at Petnica started in 5050–4850 cal BC (95% probability; Start Petnica B2; Fig. 13), probably in 4995–4900 cal BC (68% probability); the boundary between phases B2 and C occurred in 4965–4850 cal BC (95% probability; Petnica B2/C; Fig. 13), probably in 4940–4880 cal BC (68% probability); the boundary between phases C and D occurred in 4950–4845 cal BC (95% probability; Petnica B2/C; Fig. 13), probably in 4925–4860 cal BC (68% probability) and the dated sequence ended in 4935–4735 cal BC (95% probability; End Petnica D; Fig. 13), probably in 4900–4800 cal BC (68% probability).

The site of Masinske Njive is located in western Serbia on a tributary of the Kolubara River. The site was originally recorded in the 1960s and was excavated in full between 2006 and 2009 in advance of coal mining. A single phase Vinče settlement was excavated, which produced Vinče B1/B2 ceramics (M. Spasie, pers. comm.).

Three radiocarbon measurements have been obtained on samples of animal bone from settlement features. A model for the dated activity at this site has good overall agreement (Amodel: 100; Fig. 14), and indicates that this activity began in 5705–5085 cal BC (95% probability; Start Masinske B; Fig. 14), probably in 5355–5215 cal BC (68% probability), and ended in 5300–4700 cal BC (95% probability; End Masinske B; Fig. 14), probably in 5275–5070 cal BC (68% probability).

Barely 500m west of Masinske Njive, on an elevated terrace above the same tributary of the Kolubara River, lay the early Vinča A site of Jaričište 1. Although the site was recorded in the 1960s, it was only excavated between 2006 and 2010 and has since been destroyed by the Kolubara coal mine (Marić 2013). The early Vinča settlement featured several dozen pits, some containing ovens, although no wattle and daub structures were detected.

A single flax seed was dated from pit 1.137, which contained an assemblage of Vinča A pottery, indicating that these ceramics date to 5320–5205 cal BC (88% probability; NOSAMS-78623) or 5165–5135 cal BC (3% probability) or 5130–5115 cal BC (1% probability) or 5110–5075 cal BC (3% probability), probably in 5300–5240 cal BC (53% probability) or 5235–5215 cal BC (15% probability).

**The Belgrade area**

The tell site of Belo Brdo at Vinča just east of Belgrade forms the type-site for the development of Vinča pottery. The 8m of Neolithic deposits have been excavated almost constantly since 1908, when Vasić began large scale excavations. The massive assemblage of pottery from these excavations has been the subject of a series of seminal typological
studies (Fig. 2), the sequence through the tell providing relative chronology for the schemes suggested. As part of the The Times of Their Lives project, major new programmes of radiocarbon dating have been undertaken on the Vasić sequence (Tasić et al. 2016a), the excavations of the upper levels in Sector II (Tasić et al. 2015) and the sequence from a new deep sounding excavated between 2004–2014 (Tasić et al. 2016b).

Most relevant to the chronology of Vinča ceramics is the model presented by Tasić et alii (2016a,Fig. 17) for the sequence of deposits excavated by Miloje Vasić, as these excavations covered a larger area than those of all subsequent excavations combined and consequently produced by far the largest assemblage of Vinča pottery. This is a Poisson process age-depth model with the rigidity of the process defined as the 10cm spits used by Vasić to excavate the tell and record the recovered finds (Bronk Ramsey 2008; Bronk Ramsey, Lee 2013). The typological scheme for Vinča pottery published by Milojević (1943) used in this study was based on the published ceramics from this archive recorded by these spits. The age-depth model thus explicitly estimates their dates. Milojević phase A occurs between 9.3m and 8.0m, phase B1 between 8.0m and 7.0m, phase B2 between 7.0m and 6.0m, phase C between 6.0m and 4.0m, and phase D from 4.0m to the top of Vinča cultural layers at 1.3m.

On this basis, at Belo Brdo Milojević phase A begins in 5305–5255 cal BC (95% probability; Belo Brdo start A; Fig. 15), probably in 5300–5270 cal BC (68% probability). The transition between Milojević A and B1 occurs in 5210–5135 cal BC (95% probability; Belo Brdo A/B1; Fig. 15), probably in 5200–5165 cal BC (68% probability). The shift between Milojević B1 and B2 occurs in 5115–5040 cal BC (95% probability; Belo Brdo B1/B2; Fig. 15), probably in 5090–5055 cal BC (68% probability). The transition between Milojević B2 and C happens in 4935–4850 cal BC (95% probability; Belo Brdo B2/C; Fig. 15), probably in 4920–4875 cal BC (68% probability). The transition between Milojević phases C and D occurs in 4765–4680 cal BC (95% probability; Belo Brdo C/D; Fig. 15), probably in 4760–4735 cal BC (12% probability) or 4725–4690 cal BC (56% probability). Milojević (1943) placed the end of his phase D at 2.5m at Belo Brdo, but the accumulation of Vinča ceramics within the deposits of Belo Brdo continues up to a depth of 1.3m, until 4570–4460 cal BC (95% probability; Belo Brdo end D; Fig. 15), probably in 4550–4495 cal BC (68% probability).

The presence of Vinča D ceramics above relative depth of 2.5m at Belo Brdo was confirmed by excavations in Sector II undertaken between 1998 and 2009, where such ceramics occur until 4550–4485 cal BC (95% probability; fire 2; Tasić et al. 2015. Fig. 8), probably in 4545–4505 cal BC (68% probability). This date estimate for the end of Vinča D at Belo Brdo is completely independent of that provided by the age-depth model of the Vasić sequence, but the medians of these probability distributions vary by just three years. The chronological modelling of the new sounding provides much greater detail on the structural narrative of the tell but, given the small area excavated and the small quantity of material recovered, this area does not add materially to our understanding of Vinča ceramics.

The late Neolithic flat settlement at Opovo is located on a low knoll overlooking a then active meander of the Tamis River, about 25km north of Belgrade. During the 1980s five seasons of excavation recorded a total area of 340m² (Tringham et al. 1985; 1992), yielding three successive building horizons associated with late Vinča C and early Vinča D ceramics.

Thirteen radiocarbon measurements are available on animal bone (Orton 2012. Tab. 2) and unidentified
charcoal (Tab. 2) from a sequence of building hori-
zons (BH2 and 3) and associated pits. All 13 dates
are in good agreement with the site stratigraphy and
phasing, and the model has good overall agreement
(Amodel: 115; Fig. 16).

The model indicates that activity associated with
Vinča C pottery at Opovo began in 4960–4805 cal
BC (95% probability; Start Opovo C; Fig. 16), prob-
ably in 4915–4840 cal BC (68% probability), and
that the use of Vinča C pottery on the site ended in
4835–4695 cal BC (95% probability; End Opovo C;
Fig. 16), probably in 4820–4740 cal BC (68% prob-
ability). It should be noted that there are currently
no radiocarbon dates for the latest building horizon
(BH 1) at Opovo and so settlement certainly contin-
ued after this time.

Located in the south-east suburb of Belgrade of the
same name, the site of Banjica is a well-known late
Neolithic settlement. It was situated on a plateau
above the Banjica stream and was discovered during
road construction in 1921 (Todorović, Cermanović 1961). The site has yielded five settlement horizons
of wattle-and-daub structures and pits associated
with Vinča D ceramics (Tripković 2007).

Two statistically consistent measurements (T = 0.1;
T(5%) = 3.8; ν = 1; Ward, Wilson 1978) on bulk
unidentified charcoal (one including charred grain)
were obtained for features from Banjica associated
with Vinča D pottery (Tab. 2). These provided ter-
minal post quos for the end of Vinča D here of 4770–
4755 cal BC (1% probability) or 4730–4355 cal BC
(94% probability; GrN-1542), probably 4680–4635

Fig. 15. Probability distributions of Milojević (1943) ceramic phase boundaries at Vinča-Belo Brdo,
derived from the model illustrated in Tasić et alii (2016a.Fig. 17).

Fig. 16. Probability distributions of radiocarbon dates from Opovo. The format is identical to that of
Figure 7. Grey tone indicates that the sample has a possible old-wood offset. The large square brackets
down the left-hand side along with the OxCal keywords define the overall model exactly.
cal BC (13% probability) or 4620–4455 cal BC (55% probability), and 4795–4320 cal BC (GrN-1536, 95% probability), probably 4655–4640 cal BC (2% probability) or 4620–4365 cal BC (66% probability)\textsuperscript{11}.

**Central Serbia\textsuperscript{12}**

Located in central Serbia, south-west of Kragujevac, the settlement site of Grivac lies on the east bank of the Gruža River, on a wide terrace bounded by several streams. A chance discovery in 1950, it was excavated episodically between 1952 and 1994 (Bogdanović 2004). The earliest phase of occupation has Starčevo pottery, and pre-dates a settlement associated with Vinča ceramics of phases A–C, which is itself sealed by an early Iron Age barrow cemetery (Bogdanović 1977).

Six radiocarbon dates, all on samples of unidentified bulk charcoal or ‘burnt earth’, can be associated with assemblages of Vinča ceramics (Tab. 2). Bln-870 provides a \textit{terminus post quem} for the end of Vinča A of 5480–5040 cal BC (95% probability), probably of 5470–5400 cal BC (12% probability) or 5390–5205 cal BC (56% probability). The latest of the five dates associated with Vinča C ceramics\textsuperscript{13} provides a \textit{terminus post quem} for the end of Vinča C of 4960–4530 cal BC (95% probability; \textit{tpq} Grivac C; Fig. 17), probably of 4880–4680 cal BC (64% probability) or 4640–4615 cal BC (4% probability).

The site of Divostin (II) is situated in central Serbia, west of the town of Kragujevac, and on a slope between two streams in a landscape dominated by gentle hills. Small-scale excavations took place between 1967 and 1970 covering 1.65% of the estimated total site area of 15ha (McPherron, Srejović 1988). The earliest occupation on the site is associated with Starčevo pottery, but the majority of the excavated features belong to a later settlement defined by wattle and daub rectangular structures associated with late Vinča pottery.

Eleven radiocarbon dates were obtained on samples (seven unidentified bulk charcoal, one ‘burnt earth’ and three single animal bones) from a sequence of houses and pits associated with Vinča C and D pottery (Tab. 1). Two dates on bulk charcoal (Bln-867 and BM-574) are far too young for their stratigraphic position within the described sequence, and have been excluded from the model. These samples probably contained a component of intrusive charcoal. The remaining nine measurements include two sets of replicates (repeat measurements on the same bulk sample). Two measurements on unidentified charcoal from pit F117 are statistically consistent (Bln-865 and Bln-865a; \(T' = 0.2; T'(5\%) = 3.8; \nu = 1\), as are three measurements, also on unidentified charcoal, from pit 20 (F121) (Z-336a, Z-336b and Bln-898; \(T' = 2.1; T'(5\%) = 6.0; \nu = 2\)).

The model which combines these radiocarbon dates with the ceramic phasing has good overall agreement (Amodel: 113; Fig. 18), although all the samples that can be associated with Vinča C ceramics are of unidentified charcoal and so only provide \textit{terminus post quos} for the end of this phase. This model suggests that the transition between Vinča C and D ceramics at Divostin occurred in 4830–4600 cal BC (95% probability; Divostin C; Fig. 18), probably 4740–4635 cal BC (68% probability) and the use of Vinča D ceramics ended in 4710–4320 cal BC (95% probability; End Divostin D; Fig. 18), probably 4675–4535 cal BC (68% probability).

**The Morava valley and southwards**

The site of Anzabegovo is located in the eastern part of FYR of Macedonia, in an area known as Ovče Pole. It was discovered by chance during the construction of a railway line in the early 1960s, with the main excavations taking place in 1969 and 1970 (Gimbutas 1974). The multi-period settlement was first established in the early Neolithic, with activity on site occurring into the Roman period.

Two statistically consistent measurements (IJ-2329 and IJ-2411; \(T' = 1.0; T'(5\%) = 3.8; \nu = 1\)) on unidentified bulk charcoal were obtained for features associated with Vinča B pottery (Tab. 2). Given the potential for the sample to have contained a component of old wood, IJ-2329 provides a \textit{terminus post quem} for the presence of Vinča B ceramics at Anzabegovo of 5320–5025 cal BC (95% probability), probably of 5300–5025 cal BC (39% probability) or 5165–5115 cal BC (17% probability) or 5110–5075 cal BC (11% probability).

\textsuperscript{11} A third measurement is quoted by N. N. Tasić (1988:46) as ‘GrN *** 5320±150 BP’, but no further details can be traced. The Groningen laboratory has no record of this measurement, and so it was certainly produced elsewhere. It calibrates to 4455–3890 cal BC (90% probability) or 3885–3795 cal BC (5% probability).

\textsuperscript{12} Two measurements have been published by Gimbutas (1976:Tab. IV) as being from Medvednjak in central Serbia. Bln-480, however, is from Őszentiván, Hungary (Kohl, Quiutta 1970:411) and LJ-2523 is from Šventoji, Lithuania (Linick 1977:27).

\textsuperscript{13} Z-1507 is clearly much later than the other samples from this phase and has been excluded from this analysis; it is likely that the bulk sample contained an element of intrusive later charcoal.
The site of Belovode in Veliko Laole lies to the west of River Mlava, on one of its smaller tributaries. It was discovered by chance in the 1960s. The settlement was located on an ellipsoid plateau, barely 10km to the east of the Velika Morava River, and is cut in half by a small stream named Belovode (Šljivar, Jakanović 1996). The site is multi-period, with the earliest habitation occurring during the Starčevo period, followed by a longer phase of late Neolithic Vinča occupation and ending in the Late Bronze Age. The first systematic excavations took place in 1994 and continued episodically until 2015.

Nine radiocarbon dates were obtained on samples of single animal bones and antlers from a sequence of houses and associated features with Vinča A to C pottery (Borić 2009; Tab. 2). One date (OxA-14678) from the top of the sequence is far too late and almost certainly belongs to a later phase of activity and is excluded from the model. Three dates (OxA-14680, -14 683 and -14 700), with poor individual agreement with their relative stratigraphic positions, work well with the model presented in Figure 19 if treated as termini post quos (interpreted as residual animal bone within their respective contexts). If this interpretation is applied then the model, based on the stratigraphy, pottery phasing (A to C) and the radiocarbon dates, has good overall agreement (Amo dell: 102; Fig. 19).

The model indicates that the activity, associated with Vinča A to C pottery, started at Belovode in 5795–5230 cal BC (95% probability; Start Belovode A; Fig. 19), probably in 5515–5310 cal BC (68% probability); that the transition from Vinča A to B occurred in 5365–5075 cal BC (95% probability; Belovode A/B; Fig. 19), probably in 5320–5165 cal BC (68% probability); that the transition from Vinča B to C occurred in 5150–4645 cal BC (95% probability; Belovode B/C; Fig. 19), probably in 5050–4735 cal BC.
The use of Vinča C ceramics at Belovode ended in 4775–4205 cal BC (95% probability; End Belovode C; Fig. 19), probably in 4705–4495 cal BC (68% probability).

Located in a village west of the town of Prokuplje, the site of Pločnik lies on an elevated terrace of the Toplica River. It was discovered in the 1920s during the construction of a railway line and was excavated episodically until 2013 (Stalio 1964; 1973). The site is best known for the find of approx. 17kg of copper implements excavated from buildings and hoards associated with a late phase of Vinča culture (Stjivar et al. 2010).

Eight radiocarbon measurements, all on single animal bones, were obtained for features associated with houses within the settlement (Tab. 2). The dated features contained Vinča B pottery and ‘Gradac’ pottery. In this area the site begins with the use of Vinča B1 (D. Stjivar, pers. comm.), and all the dated samples are from contexts below the ‘Gradac’ layer except for OxA-14685 (Borić 2009.Figs. 22–23). Samples from sequences of deposits were dated in trenches 14 and 15, and all the radiocarbon dates are in good agreement with these stratigraphic sequences and the pottery phasing (Amodel: 102; Fig. 20).

The first use of Vinča B1 ceramics at Pločnik occurred in 5350–5060 cal BC (95% probability; Start Pločnik B1; Fig. 20), probably in 5240–5110 cal BC (68% probability). Vinča B ceramics ended here in 5030–4755 cal BC (95% probability; End Pločnik B2; Fig. 20) probably in 4985–4860 cal BC (68% probability). Trench 16 contained features associated with ‘Gradac’ pottery. A single radiocarbon sample associated with this ceramic phase provides a terminus ante quem for the start of Milojčić phase C and a terminus post quem for the end of Milojčić phase D at Pločnik of 4710–4530 cal BC (95% probability; OxA-14685; Tab. 2), probably of 4685–4630 cal BC (31% probability) or 4625–4555 cal BC (37% probability).

The site of Oreškovica lies on a hill dominating the surrounding territory around the village of the same name. It is approx. 6ha in size, and is surrounded by at least two enclosure ditches. It is a single-phase settlement associated with Vinča B pottery. Even though it was known by the mid-1970s it was only excavated for the first time in 2013 (Borić et al. in preparation).

Six radiocarbon dates, all on single samples of animal bone (two of them articulating) are currently available (Tab. 2). A model combining these results...
Fig. 20. Probability distributions of radiocarbon dates from Ploćnik. The format is identical to that of Figure 7. The large square brackets down the left-hand side along with the OxCal keywords define the overall model exactly.

Fig. 21. Probability distributions of radiocarbon dates from Oreškovića. The format is identical to that of Figure 7. The large square brackets down the left-hand side along with the OxCal keywords define the overall model exactly.

with the stratigraphic sequence is shown in Fig. 21, and has good overall agreement (Amodel: 105; Fig. 21). This suggests that the settlement at Oreškovića (and so Vinča B ceramics) began in 5400–5080 cal BC (95% probability; Start Oreškovića B; Fig. 21), probably in 5335–5210 cal BC (67% probability) or 5165–5155 cal BC (1% probability), and ended in 5215–4935 cal BC (95% probability; End Oreškovića B; Fig. 21), probably in 5200–5180 cal BC (4% probability) or 5165–5030 cal BC (64% probability).

Selevac-Staro Selo site lies in the Šumadija area, to the west of the lowest part of the Velika Morava River valley, barely 22km south of its confluence with the Danube (Tringham, Krstić 1990a). The site is located 4.8km east of the modern village of the same name on elevated ground west of the river. The site was recognised in 1968, with small-scale excavations taking place until 1970 and again in 1973. The Selevac Archaeological Project ran from 1976 until 1981, and yielded settlement remains of the Late Neolithic Vinča period.

Twelve radiocarbon dates for Selevac were obtained on samples (bulk charcoal and bulk cereal grain) from a sequence of houses and associated features with Vinča B1 to C pottery (Tab. 2). We have used the ceramic phasing for this sequence presented by Schier (1995. Figs. 144–5), although unfortunately all the dates associated with Vinča B2 and C ceramics are on unidentified charcoal and so can only be included in the model as termini post quos. This model is shown in Fig. 22, which has good agreement (Amodel: 100). Generally, measurements from the Rudjer Bošković Institute, Zagreb, are likely to
be on average 77 years too young (Horvatinič et al. 1990.299). In this case, however, it can be noted that the two measurements in question (Z-233a–b) are statistically consistent with a third from La Jolla (LJ-2521; T' = 0.4; T(5%) = 6.0; ν = 2) and so they are probably accurate.

The model indicates that this activity, associated with Vinča B1 pottery, started in 6800–6685 cal BC (2% probability; Start Selevac B1; Fig. 22) or 6340–4960 cal BC (93% probability), probably in 5525–5010 cal BC (68% probability). The transition between Vinča B1 and B2 occurred here in 5210–3585 cal BC (95% probability; Selevac B1/B2; Fig. 22), probably in 5165–4655 cal BC (68% probability). The dated occupation at Selevac ended in 4580–2460 cal BC (78% probability; End Selevac C; Fig. 22) or 2195–1495 cal BC (17% probability), probably in 4565–3190 cal BC (61% probability) or 1770–1495 cal BC (7% probability).

The site of Predionica is located in a suburb of Pristina in Kosovo. It was excavated in 1955 and 1956 in advance of the construction of a factory building. It yielded a late Neolithic settlement with three building horizons (Galović 1959). A single sample of oak charcoal was dated from a fire installation associated with Vinča A ceramics, and provides a terminus post quem of 5470–5400 cal BC (6% probability; Bln-435) or 5390–5045 cal BC (89% probability), probably of 5360–5205 cal BC (57% probability) or 5165–5135 cal BC (5% probability) or 5130–5115 cal BC (2% probability) or 5110–5100 cal BC (1% probability) or 5095–5075 cal BC (3% probability) for the end of Vinča A at this location.

The site of Valač is located in the north-west part of Kosovo, near the town of Kosovska Mitrovica. The site is located on a terraced hill on the edge of the Ibar River valley, and it appears to have been defended by a palisade and a stone wall (N. Tasić 1960). It was excavated briefly in 1957. A single measurement on a bulk sample of charred acorns and peas from a pit associated with Vinča D ceramics dates this assemblage to 4960–4545 cal BC (95% probability; Bln-436), probably to 4900–4865 cal BC (7% probability) or 4855–4685 cal BC (61% probability). Beran Krš is located on a dominant ridge on the left bank of the river Lim, approx. 3km from the town of Berane in Montenegro. Small test trenches were dug in 1961, but the main research excavations were undertaken in 1975 and 1976. The settlement consisted of several building horizons belonging to the Vinča period (Marković 1985).

Two measurements on unidentified bulk charcoal are available from two stratigraphically related deposits (Tab. 2). The published contextual details, however,

---

**Fig. 22.** Probability distributions of radiocarbon dates from Selevac. The format is identical to that of Figure 7. Grey tone indicates that the sample has a possible old-wood offset. The large square brackets down the left-hand side along with the OxCal keywords define the overall model exactly.
ever, differ. Z-491 is attributed to Level VII and Z-492 to Level XIII (Srdić et al. 1977.474), but also to Levels III and IV/Horizon Ila (Marković 1985.70). Here, we follow Čedomir Marković (1985.72) in interpreting both dates as termini post quos for the end of Vinča C ceramics at this location, of 5205–5165 cal BC (2% probability; Z-491) or 5075–4765 cal BC (93% probability), probably of 5000–4840 cal BC (68% probability), and of 5210–5160 cal BC (1% probability; Z-492) or 5080–4440 cal BC (92% probability), probably of 4930–4920 cal BC (1% probability) or 4910–4545 cal BC (67% probability). It should be noted that both measurements are from the Rudjer Bošković Institute, Zagreb, and it is likely that the measurements are on average 77 radiocarbon years too young (Horvatić et al. 1990.299).

The site of Donje Vranje in the southern Morava valley was excavated in advance of road construction in June 2013 (Kapuran et al. 2016). Several pits containing Vinča B2 ceramics were recorded. A single radiocarbon date on a disarticulated animal bone was dated from pit 1, providing a date of 5295–5240 cal BC (9% probability; SUERC-57927) or 5235–5050 cal BC (86% probability), probably of 5220–5200 cal BC (10% probability) or 5175–5070 cal BC (58% probability) for the use of Vinča B2 ceramics on the site.

The Danube downstream of Vinča-Belo Brdo
A single sample of unidentified charcoal has been dated from pit 21 at Gornea, providing a terminus post quem of 4895–4865 cal BC (2% probability; BM-1124) or 4850–4585 cal BC (93% probability), probably of 4825–4815 cal BC (3% probability) or 4805–4685 cal BC (65% probability) for the associated assemblage of Vinča A ceramics (Burleigh, Houston 1979.350). A bulk sample of charred grain from Liubcova (László 1997) has been dated from a context associated with Vinča B2 pottery, dating it to 5320–4905 cal BC (95% probability; Bln-2133), probably to 5225–5000 cal BC (68% probability).

The site of Rudna Glava is located in the village of the same name on a steep slope above it. The location is about 20 km south of the Danube in the area of the Iron Gorge (Jovanović 1982). Rudna Glava is best known for its early copper metallurgy and was the first copper ore mine to be excavated in the Balkans. Discovered in the mid-1960s, the first archaeological survey took place in 1968, followed by several seasons of excavations which uncovered multiple prehistoric shafts cut vertically into the cliff face.

Fourteen radiocarbon measurements are available on samples from Rudna Glava (Borić 2009.255), but only eight of these appear to be associated with Vinča ceramics. These have been assigned to the Gradac phase (Jovanović 1982; 1994) which here we equate broadly with Miločić phases C and D. The relationships between the dated material and the ceramics, however, are not straightforward. The deposition of hoards in which the best preserved and diagnostically most sensitive vessels were found was probably structured and possibly ritualised. This may have taken place after a long period of use of the mining shafts, and it is also possible that the hoards represent an accumulation over time rather than single events. In these circumstances, we have interpreted the start of the period when Vinča ceramics were deposited at Rudna Glava as a terminus post quem for the start of Miločić phase C, and the end of the period when Vinča ceramics were deposited at Rudna Glava as a terminus post quem for the end of Miločić phase D.

A model for the mining activities at Rudna Glava associated with Vinča C and D pottery is shown in Figure 23. A weighted mean has been taken on the statistically consistent measurements on antler RG8 before incorporation in the model (OxA-14624–5; T = 0.2, T(5%) = 3.8, v = 1), which has good overall agreement (Amodel: 97; Fig. 23).

Three measurements (BM-1589, 6900±1000 BP, 8640–3780 cal BC (95% probability); OxA-14623, 7198±36 BP, 6205–5155 cal BC (8% probability); or 6115–5995 cal BC (87% probability); OxA-14627, 6665±36 BP, 5645–5520 cal BC (95% probability)) appear to indicate use of the mining complex in the earlier part of the seventh millennium cal BC. The collagen in all these samples, however, was poorly preserved and so there must be some doubt over the accuracy of these dates. One further sample appears to indicate further use of the mines in the Copper Age (OxA-14676, 4273±32 BP, 3005–2990 cal BC (1% probability) or 2930–2865 cal BC (91% probability) or 2805–2775 cal BC (3% probability)). Two of the Vinča period dates do not appear to be associated with ceramics and are not included in the model presented here (OxA-16585, 5816±35BP, 4780–4550 cal BC (95% probability); OxA-14699, 5974±39 BP, 4975–4765 cal BC (94% probability) or 4755–4740 cal BC (1% probability)).
A timescape for Vinča pottery

We begin by constructing a chronological model, in which the use of Vinča ceramics forms a continuous and relatively constant phase of activity, opening with the start of Milojević phase A and ending with the end of Milojević phase D (Fig. 24). The start of Milojević phase A is constrained to be earlier than the start of Milojević phase B1 in this model; the start of B1 is constrained to be earlier than the start of B2; the start of B2 is constrained to be earlier than the start of C; and the start of C is constrained to be earlier than the start of D. The start of phase B (sites where we are unsure whether the ceramics are phase B1 or B2) is also constrained to be later than the start of Milojević phase A. Since we are uncertain whether the transition from one phase to the next happened at the same time everywhere, we have not constrained the end of phase A to be earlier than the start of phase B1, for example. We have however constrained the end of Milojević phase A to be earlier than the start of Milojević phase C and the end of Milojević phases B1 and B2 (and the combined phase B) to be earlier than the start of Milojević phase D. We believe these constraints to be reasonable, since there appear to be no closed assemblages containing both Vinča A and Vinča C pottery, or both Vinča B and Vinča D pottery.15

This approach means that we can examine whether there is any overlap between the use of ceramics assigned to successive phases in the Milojević scheme. Where there are more than three radiocarbon dates for a site, key parameters from the site-based models described above are imported as likelihoods in the synthetic models. For example, in the model component relating to the currency of Vinča A ceramics (Fig. 25), Vinča Belo Brdo is represented by two parameters – Belo Brdo start A and Belo Brdo A/B1 – which means that the 19 radiocarbon measurements from samples recovered between the depths of 9.3m and 8.0m in the Vasić sequence are not disproportionally weighted in the model in comparison with sites with fewer dates. Where there are one or two dates on short-lived materials securely associated with a ceramic phase, these are included fully in the model (e.g., Deb-2579 from Satchinez; Fig. 25). In other cases, where there are one or two results on charred plant material that might have included a component of old wood, the dates are modelled as termini post quos for the end of the phase. These distributions are shown in grey (e.g., Bln-435, a sample of oak charcoal from Predionica; Fig. 25). In a few cases, dates are clearly misfits, and have been excluded from the modelling (e.g., BM-1124, a sample of unidentified charcoal from Gornea) which is more than 400 years later than any other sample associated with Vinča A ceramics and must have contained component of intrusive material. These distributions are shown in red and the parameter name is followed by ‘?’.

The overall form of this chronological model (Model 1) is illustrated in Fig. 24 with its components illustrated in Figs. 25, 27, 29, 31–32 and 35. It is defined exactly by the CQL2 keywords and structure provided as supplementary information (Vinca_Milojevic_Model_1.oxcal).

---

15 As part of the preliminary modelling undertaken for this study, we constructed a model which included no relative sequence between the phases of Vinča ceramics. This model suggests that start A is earlier than start B1 (87% probable), that start B1 is earlier than start B2 (95% probable), that start B2 is earlier than start C (96% probable), and that start C is earlier than start D (88% probable). This model also suggests that end A is earlier than start C (96% probable), and that end B1 and end B2 are earlier than start D (85% and 62% probable respectively).
The component of this model relating to the currency of Vinča A ceramics is shown in Fig. 25. It suggests that this ceramic phase begun in 5405–5310 cal BC (95% probability; start A; Fig. 25), probably in 5365–5320 cal BC (68% probability). The use of Vinča A ceramics ended in 5205–5070 cal BC (95% probability; end A; Fig. 25), probably in 5200–5130 cal BC (68% probability). Vinča A ceramics were thus in use for a period of 125–295 years (95% probability; duration A; Fig. 38), probably for 140–230 years (68% probability).

The Vinča network appears to have been established very quickly – within the space of one or two human generations. Sites as widely spaced as Szederkény-Kukorica-dűlő and Belovode were probably founded in the generation before 5300 cal BC (Figs. 25 and 26). Other sites came into being over the succeeding century, including the Vinča settlement at Belo Brdo itself, which as suspected by Lazarovici (1979.105–106, Tab. 7, 122–123) was not among the very first foundations. We have modelled radiocarbon dates from sites from the northern and the western periphery of the Vinča A network, as well as from its centre. Although there are known sites with characteristic Vinča A forms in the southern and eastern periphery of the network, either they are lacking radiocarbon dates, or the association between pottery phases and radiocarbon dates is not secure. Currently Szederkény-Kukorica-dűlő in the extreme northwest of the network is the earliest known dated site with Vinča ceramics (on present evidence it is 60% probable that it was established before Belovode: Fig. 25). It is not possible to disentangle the direction of innovation without dating many more sites at the generational precision provided by ToTL at Szederkény-Kukorica-dűlő, Versend and Belo Brdo. The network was established so quickly that we need to trace the foundations of different sites to within a few decades across the latter part of the 54th and the earlier part of the 53rd century cal BC.

Recent formal modelling of the earliest (älteste) LBK, however, allows us to compare the date when the Vinča network was established with the time when LBK ceramics rapidly spread across much of north and north-west Europe. Jakucs et alii (2016. Figs. 17–22) present three alternative models for
the time when the LBK spread beyond the initial locus of its development in Transdanubia. Whatever the dating of its formative phase, all these models agree in placing this rapid expansion in the middle decades of the 54th century cal BC (Fig. 41). This is precisely the time when the first Vinča pottery was made. The potential implications of this are explored in the Discussion below.

The component of the model relating to the current of Vinča B1 ceramics is shown in Fig. 27. It suggests that this ceramic phase begun in 5355–5195 cal BC (95% probability; start B1; Fig. 27), probably in 5330–5245 cal BC (68% probability). The use of Vinča B1 ceramics ended in 5045–4800 cal BC (95% probability; end B1; Fig. 27), probably in 5040–4915 cal BC (68% probability). Vinča B1 ceramics were thus in use for a period of 185–505 years (95% probability; duration B1; Fig. 38), probably for 230–395 years (68% probability).

There is considerable uncertainty around the dating of Vinča B1 ceramics since, with the exception of Belo Brdo itself, all the sites are poorly dated. Such data as we have, however, are consistent with a relatively swift transition from Vinča A at the beginning of the 52nd century cal BC. There was a period of overlap (100% probable), as is reflected in Lazarevici’s (1991.19–20, 27) phase A3/B1. This period of overlap lasted for 25–245 years (95% probability; A/B1; Fig. 39), probably for 70–185 years (68% probability).
There is a marked increase in the density of sites producing Vinča B1 ceramics (Fig. 28) in comparison to sites producing Vinča A ceramics (Fig. 26). It appears, however, that Vinča ceramics are no longer found upstream of the Danube confluence with the Tisza, although their continuing influence can be traced in the development of Sopot-type pottery. Sites with Vinča pottery are still found along the Tisza and Mureș valleys.

The component of the model relating to the currency of Vinča B2 ceramics is shown in Fig. 29. It suggests that this ceramic phase began in 5295–5105 cal BC (95% probability; start B2; Fig. 29), probably in 5285–5270 cal BC (3% probability), or in 5230–5130 cal BC (65% probability). The use of Vinča B2 ceramics ended in 4920–4770 cal BC (95% probability; end B2; Fig. 29), probably in 4905–4830 cal BC (68% probability). Vinča B2 ceramics were thus in use for a period of 220–470 years (95% probability; duration B2; Fig. 38), probably for 270–405 years (68% probability).

Again there was clearly a period of overlap (100% probable) between Vinča B1 and Vinča B2 pottery. This period of overlap lasted for 90–425 years (95% probability; B1/B2; Fig. 39), probably for 130–310 years (68% probability).

The number of sites producing Vinča B2 pottery is greater than those producing Vinča B1 pottery, and its distribution extends further to the west and south-east. Sites in the lower Tisza valley, however, appear no longer to have access to Vinča pottery (Fig. 30), perhaps because the Szahálhát network was expanding from the north at this time1166. The spatial distribution of the network appears to have reached its greatest extent in this phase (possibly in the later part of it, equivalent to Schier (1995) phase C1), spreading from Kaloševiš in the far west as far as Anzabegovo to the south-east and Ocna Sibiului to the north-east.

The component of the model relating to the currency of Vinča pottery which can only be assigned to Milojeviš phases B1 or B2 is shown in Figure 31. It suggests that this combined phase began in 5360–5235 cal BC (95% probability; start B; Fig. 31), probably in 5355–5275 cal BC (68% probability). This is entirely compatible with the estimated date for the

* We are aware of a number of sites in Bulgaria (e.g., Bulgarchevo) containing ceramic types which form part of the Vinča repertoire. They also occur, however, more widely in the area to the east of the Vinča network and so cannot be considered to be exclusively diagnostic Vinča forms. This contrasts with sites (e.g., Satchinez) which contain diagnostic Vinča pottery in contexts mixed with other clearly non-Vinča forms.

16 The Szakálhát culture evolves during Vinča B1 along the middle Tisza area. At the time of Vinča B2 Szakálhát and the closely related Bucovăţ group dominate south-east Hungary and the western part of the Romanian Banat, extending well into the Serbian Vojvodina (Goldman 1985.64–66; Horváth 1983.90; Goldman, Goldman-Szenaszky 1991.194).
start of Milojčić phase B1 presented above (Fig. 27). This combined phase ended in 5070–4770 cal BC (95% probability; end B; Fig. 31), probably in 5010–4825 cal BC (68% probability). This posterior date estimate is entirely compatible with the estimated date for the end of Milojčić phase B2 presented above (Fig. 29), but is considerably less precise.

The component of the model relating to the currency of Vinča C ceramics is shown in Fig. 32. One distribution has been excluded from the model. This is the transition from Vinča C to Vinča D pottery at Petnica, which is 150 years earlier than the same transition from anywhere else. This seems implausible, since Petnica is a small occupation site which is not even on one of the major rivers that clearly provided the connectivity of the network; moreover, the stratigraphy of this site is not unproblematic (Orton 2012:16–20). Three distributions (shown in blue) for assemblages that can only be classified as either Vinča C or Vinča D are included as termini ante quos for the start of Vinča C. The model suggests that Vinča C began in 5115–4895 cal BC (95% probability; start C; Fig. 32), probably in 5020–4905 cal BC (68% probability). The use of Vinča C ceramics ended in 4620–4400 cal BC (95% probability; end C; Fig. 32), probably in 4550–4445 cal BC (68% probability). Vinča C ceramics were thus in use for a period of 325–650 years (95% probability; duration C; Fig. 38), probably for 390–555 years (68% probability).

The distribution of sites producing Vinča C pottery (Fig. 33) is very similar to that of sites producing Vinča B2 pottery (Fig. 30). Vinča ceramics are still absent from sites in the lower reaches of the Tisza valley but appear to occur on more sites in the Timiș valley.

Where we have been able to date the transition from Vinča B2 to Vinča C ceramics directly, the date estimates fall in a tight group in the generations around 4900 cal BC (Fig. 34). There was clearly an overlap between these two ceramic phases (100% probable). This period of overlap lasted for 20–260 years (95% probability; B2/C; Fig. 39), probably for 50–180 years (68% probability).

The component of the model relating to the currency of Vinča D ceramics is shown in Figure 35. It suggests that this ceramic phase began in 4870–4725 cal BC (95% probability; start D; Fig. 35), probably in 4810–4740 cal BC (68% probability). The use of Vinča D ceramics ended in 4151–4360 cal BC (95% probability; end D; Fig. 35), probably in 4140–4145 cal BC (68% probability). Vinča D ceramics were thus in use for a period of 250–455 years (95% probability; duration D; Fig. 38), probably for 285–390 years (68% probability).

The distribution of sites with Vinča D ceramics is clearly concentrated to the south of the Danube with only a few sites in the southern Banat appearing on the north bank (Fig. 36). No pure Vinča D assemblages occur in Transylvania but it seems that the
distribution of this type of pottery reaches the Sofia basin to the east.

Vinča D ceramics began after Vinča C pottery had first appeared, and endured for longer (100% probable) (Fig. 37). Vinča C ceramics may have been in use for most of the currency of Vinča D types, if the late dating of Vinča C at Belovode, Selevac and Gornja Tuzla is robust (Fig. 32). The majority of dated sites came to an end in the 46th or the earlier part of the 45th century cal BC (Fig. 35).

A summary of the dating of the phases of Vinča pottery suggested by Milojčić (1943) is shown in Figure 37. Vinča pottery was clearly in use across a wide area from the mid-54th century cal BC to the mid-45th century cal BC.

Each of these phases endured for several centuries, Vinča A being the briefest and Vinča C being the longest (Fig. 38). Successive phases routinely overlapped by a century or two (Fig. 39), but phases C and D overlapped by around 300 years. Either the connectivity of the network was loosening in the later centuries of its existence and there was more diversity in contemporary pottery forms, or our dating of the latest sites with Vinča C ceramics (in particular Belovode, Gornja Tuzla and Selevac) is anomalous. The implications of this are discussed further below.

**Sensitivity analyses**

We further explore the robustness of the results from Model 1 by constructing an alternative model which treats the five Milojčić phases as sequential and abutting (cf. Fig. 2). This means, for example, that there is no ending to phase A and no beginning to phase B1 but rather an abrupt transition from A to B1. The overall form of this model is illustrated in Fig. 40. The components of the model are similar to those illustrated in Figs. 25, 27, 29–2 and 35 but where we have formal estimates for the dates of transitions at particular sites these have been combined in the model. The model is defined exactly by the CQL2 keywords and structure provided as supplementary information (Vinca_Milojcic_Model_2. oxcal).

We must make clear from the outset that this alternative model, Model 2, has poor overall agreement between the radiocarbon dates and the strict sequence of non-overlapping abutting phases (A: 4; Fig. 40). This means that it is statistically implausible. Where the radiocarbon dates contradict the typological sequence is, however, enlightening and helps us to interpret the results of the preferred model.

All the data in Milojčić Phases A and B1 have good agreement with a strict sequence between them, and the two sites where we have been able to formally
A Vinča potscape: formal chronological models for the use and development of Vinča ceramics in south-east Europe

model the A/B1 boundary (at Belovode and Belo Brdo) have produced compatible date estimates for this transition (Acomb = 108, An = 50, n = 2). It seems likely therefore that the transition from Vinča A to B1 occurs relatively swiftly within the first decades of the 52nd century cal BC.

Three distributions have poor agreement with a strict sequence between Milojčić phases B1 and B2. MAMS-22668, an animal bone from Potporanj (A: 13), and SUERC-57927, an animal bone from a pit at Donje Vranje (A: 21), are both rather earlier than would be expected if the strict succession of Vinča B1 and B2 is valid everywhere. In Vinča B1, build H3d+c from Uivar is rather later than would be expected, on the same basis, for an assemblage of Vinča B1 ceramics. We note, however, that this Uivar assemblage is thought to be an imitation by local potters of Vinča B1 types, and so the archetype of the imitation may not have been new when copied. A variant of Model 2, which excludes build H3d+c from Uivar, brings the dates from Potporanj and Donje Vranje into good agreement with the sequence (A: 87 and A: 88, respectively). The two sites where we have calculated the transition from B1 to B2 directly (Belo Brdo and Selevac) have produced date estimates that are compatible (Acomb = 106, An = 50, n = 2). On this basis, it again seems likely that the transition from Vinča B1 to B2 was relatively swift, in the decades around or just after 5100 cal BC.17

All the data from Milojčić phases B2 and C are compatible with a strict sequence between them, and the three sites where we have been able to formally model the B2/C transition (Petnica, Belo Brdo and Belovode) have produced date estimates that are also compatible (Acomb = 123, An = 41, n = 3). Model 2 therefore agrees with our inference from Model 1 (see Fig. 34) that this transition occurred swiftly in the decades around or slightly before 4900 cal BC. The data from Vinča C, however, are not compatible with a strict sequence to Vinča D. Posterior distributions for the end of Vinča C from Belovode (A: 56), Selevac (A: 2) and Gornja Tuzla (A: 0 and A: 47) are all later than would be expected.

17 Early dates from Masinske Nijve and Oreškovica may perhaps impart caution as to the speed of this transition, since the posterior density estimates for the start of both sites, currently assigned only generally to Vinča B, have poor agreement (A: 10 and A: 40, respectively) with the strict succession from Vinča A to B.
if Vinča C ceramics ceased to circulate at the time when Vinča D ceramics were first introduced. Of the three sites where we have formally modelled the C/D transition (Gomolava, Belo Brdo and Divostin), the date estimate for the transition at Gomolava is substantially earlier (by almost a century; A: 2) than the other two posterior distributions (A:comb = 76, An = 41, n = 3).

It is not impossible that there was actually a swift transition from Vinča C to Vinča D in the first decades of the 47th century cal BC. The dates from Selevac and Gornja Tuzla were on conventional bulk samples of charred plant material that could have contained an element of intrusive, later material, although the date estimate from Gomolava appears to be robust, since it rests on no fewer than ten results on samples of animal bone (Fig. 12). If the earliest sample associated with Vinča D at Gomolava, OxA-14710, a bone tool, however, was residual, then the estimated date of the transition here would shift more in line with those from Belo Brdo and Divostin. On the whole, however, the cumulative weight of these strands of evidence may be sufficient to indicate that there was really a considerable overlap between the use of Vinča C and Vinča D ceramics. This has implications for the connectivity of the cultural network in the final centuries of its existence.

In conclusion, this sensitivity analysis suggests that, within the precision obtainable by the data that are currently available, the chest-of-drawers model of sequential ceramic phases is not importantly wrong, except perhaps in relation to the transition between Vinča C and Vinča D, where a significant period of concurrent use seems probable.

Discussion

Over 45 years later, the claim of Colin Renfrew (1970.53) that analysis of the development of the Vinča culture ‘represents one of the most challenging tasks in European prehistory’ remains valid. In our introduction, we outlined many aspects of the Vinča culture, but here we are going to concentrate, first, on beginnings or origins, and secondly, on the character of the developed stages of the phenomenon. What insights do the better timings provided by formally modelled estimates provide?

We need, first, to set out briefly the interpretive frame within which better timings can be interrogated. As one of us has recently sketched (Borić 2015. 159–162), three main approaches to the study of the Vinča culture can be identified in past research: culture-historical, processual and post-processual. Each of these has given rather different answers to the related questions of beginnings and the nature
A Vinča potscape: formal chronological models for the use and development of Vinča ceramics in south-east Europe

The culture-historical approach has been dominant among researchers in the region, though not universally so (see, for example, Korošec 1965). Out of the total range of Vinča material culture, this approach has placed heavy reliance on pottery typology (charted by Chapman 1981. Ch. 4). For origins, it sees disjuncture in longer-term sequences, and derives fresh beginnings from the outside, on a large scale and potentially from long distances: in some accounts from as far afield as Anatolia (Efe 2000; Garašanin 2000). There was little further explicit reflection on the character and conditions of different kinds of population displacement and colonisation. Subsequent developments were largely left to take care of themselves, except in those variants which saw another wave of arrivals of southern origin: the so-called Vinča C ‘shock’ already noted above. The approach did, however, create coherent (though often varying) narratives about the broad history of a perceived social entity.

The processual approach to the Vinča culture was characteristically concerned with the playing out of local or regional conditions. In the quotation above, Colin Renfrew (1970.53) elaborated that the Vinča culture ‘developed in these areas through the operation of local factors, and must be explained in terms of these factors’, though he certainly took seriously the previous claims for outside involvement. In terms of origins, continuity was sought, though on then imprecisely defined timescales, especially in material sequences, including those of pottery, and in landscape use (Chapman 1981.5, Ch. 4). Consistent with this kind of focus, the concept of the autonomous household was proposed as a major agent of change in the processual narrative of the development and eventual break-up of the Vinča culture (Tringham, Krstić 1990b.581). Broad trends rather than precise chronology were the temporal currency. Post-processual approaches have focused on selected situations. An important sketch of the development of Vinča-Belo Brdo itself was offered, with careful consideration given to the character and sources of material in use at the tell; the resulting account asserting the early dominance and eventual slow decline of the site implies a wider narrative, but does not explicitly document it (Chapman 2000.203–220). Other themes, broadly classifiable as post-processual, have included the nature of deposition and symbolic dimensions of houses (Borić 2008; 2015.162; Trpišković 2007; 2013; Crnobrnja et al. 2009; Spasić, Živanović 2015). Wider narratives of beginnings and subsequent development, however, have often been laid aside in this change of focus, and for the most part, chronological precision has not been a major concern of such contextual approaches.

Other interpretive approaches might be advocated. Culture evolutionary theory (as variously set out in, for example, Shennan 2009; Bentley et al. 2011) could be advocated (Borić 2015.189–191). The
recent fashion of ascribing much greater agency to things – the ontological turn (among a host of others, see Olsen 2010; Hodder 2012; Rivzi 2015; see also Borić 2015.191–193) – could be extended to the rich material assemblages of the Vinča culture. Here, we choose not to follow either. The former tends to dehumanise complex processes of social interaction, and it is hard to escape the neo-Darwinian baggage that comes with it. The latter requires a much longer debate than we have space for here. It deliberately decentres human agency (see also Van Dyke 2015), much more precise narratives for which we are seeking to establish in this paper (cf. Drašovean et al. submitted). If both approaches are for further discussion elsewhere, what we have found helpful are some of the terms and concepts

Fig. 32. Probability distributions of dates associated with Milojević Vinča C ceramics (key parameters for individual sites have been imported from the models defined or cited in Figs. 4–23). The format is identical to that of Figure 7 (grey tone indicates that a sample has a possible old-wood offset; red indicates a distribution excluded from the model; blue indicates a distribution modelled as a terminus ante quem). The model is defined exactly by the OxCal keywords and structure provided as supplementary information (Vinca_Milojevic_Model_1.oxcal).
A Vinča potscape: formal chronological models for the use and development of Vinča ceramics in south-east Europe

From ongoing debates on themes of hybridity and ethnogenesis, in the field of the archaeology of colonialism. As a proposition which is useful for us to reflect upon, Matthew Liebmann (2013.27) has asserted of the three primary means by which new things come into being, that invention (“the creation of wholly original objects, styles and technologies”) is the rarest, that divergence (or evolution, by which “changes to an existing form through time result in the eventual creation of multiple separate types through splitting and branching”) has been the focus of much archaeological attention, and that convergence, or “creation through recombination”, is “probably the most common”, though less studied in past research by archaeologists. In these terms, it seems clear that the culture-historical approach to the Vinča culture has favoured some version of invention for origins and kinds of divergence for subsequent development, while the processual approach has largely plumped for divergence; the possibility of convergence, in these terms, appears largely to have been neglected.

This is not the place to review in detail all the competing notions such as hybridity, acculturation, syncretism, bricolage, creolisation and mestizaje, or the advantages and disadvantages of their deployment (Liebmann 2013; 2015; Stillman 2015; and references), but it is useful to retain the sense of grounded detail which such studies offer. Matthew Liebmann (2015.331–334), for example, looks at the production of soup plates within the repertoire of Spanish-inspired Pueblo ceramics, over the specific timeframe of 1598–1700, noting an interplay of external and local factors in their design and decoration. Barbara Voss (2015.665–666) associates the wider notion of ethnogenesis with ‘historical circumstances in which practices of identification are structurally transformed’, often as the result of ‘substantive demographic shifts – aggregation, disaggregation, displacement, and migration – combined with the emergence or imposition of new structures of power’. She stresses, however, that ethnicity has to be demonstrated rather than assumed (Voss 2015.658), and questions the often lazy translation of archaeological culture into ethnic entity (Voss 2015.660).

We therefore seek to interpret the timings of Vinča ceramics presented in this paper within an approach that might broadly be classified as contextual and practice-based. Our principal evidence is that of the pottery itself, and it is important to stress that the vast majority of Vinča ceramics have been found in settlement contexts, and especially in association with houses and dwelling horizons. There is a wealth of information about later Vinča houses. Well-preserved contexts such as houses at Crkvine-Stubline, part of a local network of sites of varying size, some 40km south-west of Belgrade and Vinča-Belo Brdo...
Whittle, Bayliss, Barclay, Gaydarska, Bánffy, Borić, Drașovean, Jakucs, Marić, Orton, Pantović, Schier, Tasić and Vander Linden

(Crnobrnja et al. 2009; Crnobrnja 2012), had lots of pots in them: ‘dozens of ceramic vessels’ and ‘a large number of storage vessels’ in house 1/2008 (Spasić, Živanović 2015.220). Some of these may have been stacked on wooden shelves (Crnobrnja et al. 2009.19). There are plentiful other examples, such as at Divostin (Tripković 2010). Occasionally pots are found in the spaces outside, in between houses (Nikolić, Vuković 2008). This household setting is therefore presumably the context in which Vinča pottery was principally used, for a wide range of tasks, from food preparation (though the direct evidence for that is surprisingly sparse), storage and consumption. It may be that vessels most open to public gaze, literally passable from hand to hand, such as certain types of bowls, were the ones most likely to change the fastest through time, as evidenced in the correspondence analyses of bowls from Vinča-Belo Brdo (Schier 1996; 2000); these might also have been the vessels most likely to break (David 1972). Some forms, such as protome vessels, seem to have remained more or less unchanged through the sequence (Spasić, Crnobrnja 2014). And it is important to remember that pottery was only one element of the total materiality of the house, and other constituents such as tables, hearths

Fig. 34. Probability distributions of dates associated with the introduction of Vinča C ceramics, derived from Model 1.

Fig. 35. Probability distributions of dates associated with Milojić Vinča D ceramics (key parameters for individual sites have been imported from the models defined or cited in Figs. 4–23). The format is identical to that of Figure 7 (grey tone indicates that a sample has a possible old-wood offset; red indicates a distribution excluded from the model). The model is defined exactly by the OxCal keywords and structure provided as supplementary information (Vinca_Milojcic_Model_1.oxcal).
A Vinča potscape: formal chronological models for the use and development of Vinča ceramics in south-east Europe

...and storage facilities, which help to define a suite of eating practices (Spasić, Živanović 2015), and the layout of house interiors themselves, could have been at least as important as pottery in the creation and projection of social identities. So the context of pottery use was probably primarily associated with houses, but given the broad sharing of style seen in the wide distributions (Figs. 26, 28, 30, 33, and 36), on this basis alone it is extremely unlikely that households were autonomous; it is far more likely that groups of houses and neighbourhoods were the nodes through which intense connections were effected. On a note of caution, we have to recognise that our knowledge so far of early Vinča domestic contexts is much worse (though that helps to define a clear goal for future research). The detailed record for Vinča A contexts in Serbia, especially, is dire. By way of brief example, Trnovac has poorly defined wattle and daub structures (Jovanović 1965), while Stagari is reported to have similar structures, but these are not illustrated (Stanković 1989). Likewise, while there is detailed information on the mix of ceramic styles associated with particular longhouses at Szederkény and Versend in south-west Hungary (Jakucs et al. 2016; submitted), the material comes from flanking pits, not house floors. This lacuna hampers what we can say about the conditions of the emergence of the Vinča ceramic style.

Another gap in knowledge concerns the making of pottery. Few if any structures have been identified as being associated with pottery production; the northern part of the interior of house 8 at Banjica has been suggested as a candidate (Tripković 2007, 74, 119), but the evidence is ambiguous (Todorović, Germánek 1961). Importantly, we do not know whether all households made pottery, or if certain potters served communities at large. Whilst more data on chaînes opératoires and archaeometric analyses will help us refine our understanding of pottery production as a whole, they are of limited use to identify units and scales of production. Another avenue worth exploring would be the identification of differences in standardisation, as tentatively identified by Vuković (2011) between the sites of Vinča-Belo Brdo and Motel Slatina, assuming that they reflect levels of craft specialisation. We further note a fragment of the perforated clay floor which separated the fire chamber from the pottery chamber in a two-chambered kiln that was recovered from a lower fill of enclosure ditch F1053 at Uivar. This find provides a terminus ante quem for the use of two-chambered kilns in the production of ceramics of 4855–4755 cal BC (95% probability; dig F1053; Schier et al. forthcoming; Fig. 6.17), probably of 4830–4780 cal BC (68% probability) – a time when Vinča B2 ceramics were current (Schier 2005).

In turning then to beginnings and development, it is obvious that we have gathered up a sample that represents currently available dated sites, with a range in both the quality and quantity of samples.
Without doubt, a better dataset can be created in the future. We have also raised questions about the detail of the available typological schemes. Those can also be refined in the future. But we believe that the combination of more precise estimates of timings, order and duration, the distributions and density of known sites with diagnostic pottery through successive phases, and information about context, is sufficiently powerful to enable a preliminary reconsideration of important dimensions of the Vinča culture.

**Beginnings**

The modelled estimates for the appearance of Vinča A pottery given above suggest a rapid introduction. The earliest sites dated so far belong in the north of the distribution. The overall density of sites is not as great as in later phases. Simply in these terms, neither the spatial pattern nor the temporal distribution match what the formerly proposed big-scale migrations might be expected to have produced. Those earlier hypotheses were never accompanied by explicit consideration of either the conditions in the homeland of colonists or of the circumstances in which newcomers operated once arrived in fresh territory. That has, however, been set out elsewhere, and on a comparative (but not necessarily universal) basis, there often seems to be a process of initial scouting, followed by movement by selective groups, rather than wholesale populations (Anthony 1990; 1997). To take just one specific example, Susan Alt (2006.290, 294) set out three criteria for detecting possible migration into the American Bottom at the onset of the Mississippian phase – regional population growth, patterns of diversity and the distribution of non-local pottery types – but she also proposed a framework in which both migration and local development could be seen as components of the same process, involving convergence and hybridity.

Now it certainly seems to be the case that ceramic traits that overlap with the Vinča repertoire are found widely in the southern Balkans and northern Greece broadly in the same horizon as the appearance of Vinča ceramics. This refers to the widely distributed dark burnished wares that are variously represented among the ceramic assemblages of Karanovo III and the Late Neolithic or Tsangli phases of Bulgaria and northern Greece (Georgiev 1961; Lazarovici 1979.72–74; Efstratiou et al. 1998; Kotsakis 2014). But these dark wares are only part of much wider repertoires; there are many painted wares as well (Kotsakis 2014.61). To take just two examples, unusual circumstances of preservation in one context at Promachon-Topolnitsa on the Greek-Bulgarian border produced decorated bark, part of a wide range of pot forms and decorations (Koukouli-Chryssanthaki et al. 2007, Fig. 19), and there were some painted vessels among the mainly dark wares in phase II at Makri in Agean Thrace, informally estimated as dating after 5500 cal BC (Efstratiou et al. 1998.32). Informal estimates for the start of the northern Greek Late Neolithic are certainly compatible with the Vinča chronology set out above, but relatively few sites have so far been radiocarbon dated with rigour (see, for example, Dispilio: Facorellis et al. 2014), and there has been little Bayesian modelling so far of this horizon (Kostas Kotsakis, pers. comm.). It does seem to be the case that in these areas this horizon sees a marked increase in the number of sites and their much wider distribution across the landscape, compared with earlier settlement (Kotsakis 2014.60); the lakeside site of Dispilio (Karkanas et al. 2011) can usefully stand as a specific single example of this trend. So there is no need to disconnect processes in the southern Balkans and northern Greece from those operating further north, but it now appears a very clumsy explanation to derive all northern changes from the south.

![Fig. 37. Schematic diagram showing the currency of the different phases of Vinča ceramics proposed by Milojčić (1943) (the darker the shading the more probable that a ceramic phase was present in a particular 25-year period), derived from Model 1.](image-url)
The timing and distribution of Vinča A ceramics as set out above can be argued to better align with processual explanation of local or regional development. But things may not have been as simple as this, and that processual approach turns out, in our view, to have been far too myopic: too constrained within too narrow a spatial perspective. There is, first, still the question of how material culture developed from the Starčevo to the Vinča repertoire. Some elements of local continuity have already been noted (as proposed by Chapman 1981; Leković 1990); the Hungarian notion of ‘proto-Vinča’ elements (Mak-kay 1990) has long been debated. On their own, however, these seem insufficient, without a further assumption of rapid and extensive material changes. We know that there was a measurable gap in the occupation of Vinča-Belo Brdo itself between the Starčevo and Vinča phases (Tasić et al. 2016a; 2016b), but there is still much work to be done – and beyond the remit of this paper – to date and model the timing and tempo of this transition (see also Porčić et al. 2016). What we can stress here is the apparent synchronicity of the appearance of Vinča ceramics and the earliest LBK diaspora, as set out above. Now, entirely indigenist explanations for the appearance of the LBK (e.g., Whittle 1996) have not stood the test of time, and the increasing weight of aDNA evidence (now bolstered by genomic analysis) supports a substantial, perhaps major, element of new population dispersing into central and western Europe (among others, see Brandt et al. 2013; D. Hofmann 2015; Szécsényi-Nagy et al. 2015; Olalde et al. 2015; Hofmanová et al. 2016; Lazaridis et al. 2016). On the evidence of Szederkény and Versend in southern Hungary (Jakucs et al. 2016; submitted),

We suggest that in place of ‘the old tired accounts of migration and diffusion’ (Kotsakis 2014:65) a much more complex and challenging account needs now to be given of rapid and extensive change, that has to be seen at local, regional and inter-regional scales, which involved material transformations to suit the changing circumstances of increasing populations more widely distributed across their landscapes, and some of whom may have been caught up in processes of movement and displacement. Some strands in shifting material repertoires were very widely distributed, but those can probably best

Fig. 38. Key parameters for the duration of the phases of Vinča ceramics proposed by Milojčić (1943), derived from Model 1.

Fig. 39. Key parameters for the overlap between phases of Vinča ceramics proposed by Milojčić (1943), derived from Model 1.
be further investigated as media through which social connections across this very broad, shifting world were expressed. As a discipline, we have been comfortable debating intensely the beginnings of the Neolithic, but we have been far less successful so far in thinking through subsequent transformations.

Development

Increasing connectivity seems to define the next phases of development, from Vinča B1 through Vinča D, though we have noted difficulties above in differentiating between B1 and B2 assemblages in some areas, it seems that the trend following the A phase was towards the appearance of more sites in the landscape. The greatest density is reached overall already by the Vinča B2 phase, and that is then maintained in the Vinča C phase. On the ground, this coincides, as noted also above for northern Greece and the southern Balkans, with a spread in the distributions of sites across local landscapes (e.g., Chapman 1990), and with the appearance of more tells and larger flat sites. At this point, we can indeed perhaps best think in terms of local and regional factors at work. This appears to have been an intensifying but at the same time stable phenomenon, the timings set out above showing long continuities at a landscape scale, and to varying degrees in particular locations. The notion of the ‘shock of Vinča C’ is probably now best translated into the peak connectivity of the system, and the timings suggest that that was anyway reached earlier, in Vinča B2. There appears to be no particular need to invoke further population movement at the start of the Vinča C phase, even though the models set out above suggest a probably quite rapid transition from Vinča B2 to Vinča C ceramics. But yet again, the possibility of some small-scale displacements need not entirely be excluded. It is also worth noting that the emergence of Vinča C ceramics followed the end of the LBK, and may have coincided with a hiatus between LBK and Hinkelstein in some parts of the Rhineland (Denaire et al. in press); further east, there was probably more continuity after the end of the LBK (Link 2014), but as with beginnings, it is useful to keep an eye on the wider situation and connections.

In our view, as already hinted at in the language used throughout this paper, it is probably best in the first place to see this developed Vinča phenomenon, from Vinča B1 right through into Vinča D, as an extended social network. The overall distribution is markedly riverine, and one of us has recently sketched the connectivity in terms of ‘various influences, borrowings, emulations, exchange, trade and breeding networks’ (Borić 2015.158), underpinned by flows of material into sites and played out in the household settings described above. The culture historical approach has tended to construct a further sense of unifying or coherent group or ethnic identity. We have noted the warning of Voss (2015.660) about equating ‘ethnonyms’ with real ethnicities, and it was normal processual procedure to set that kind of interpretation aside. But it has long been apparent that the Vinča phenomenon was long-lasting and in that sense stable, which the more precise timings set out in this paper serve only to underline. Without removing local differences, there must have been much that was shared throughout the Vinča network, and from widespread, common practices there surely came a shared way of acting in and understanding the world. The virtual absence of formal or archaeologically visible mortuary practice throughout the network and the wide distributions of altars, anthropomorphic figurines (Tasić 2016), face-lids and masks, may also speak to widely shared ways of thought. Cumulatively, this perhaps gets us closer...
to Voss’s (2015:658, quoting Vermeulen, Govers 1994) very general definition of ethnicity as a “consciousness of difference”, “that is negotiated both through external debates about differences between ‘us’ and ‘them’ and through internal contests over community self-definition”. But it is far from clear that the Vinča network had rigidly defined or sharp boundaries, even though from Vinča B1 onwards different kinds of ceramics were preferred in southern Hungary, for example. And whether the network at its peak projected “ideologies of shared and divergent history, ancestry, and tradition” (Voss 2015:658), in contrast to or opposition to other contemporaneous cultural groupings, perhaps also remains a moot point; wider connectivity seems to have been at least as important as local or regional self-definition.

Endings

Some of the most intriguing questions raised by our study relate to the Vinča D phase. Though this now appears shorter than frequently suggested in the past, it nonetheless represents overall a substantive continuation of existing practice. Though this was the phase in which some tells began to be abandoned, others, such as Vinča-Belo Brdo itself (Tasić et al. 2015; 2016a; 2016b), continued to rise steadily, until endings perhaps mainly in the 46th century cal BC. Simply on the basis of two well-dated sites, Vinča-Belo Brdo and Uivar (Drăsovean et al. submitted), it could be the case that house burnings became more frequent in the last two centuries or so of the Vinča network. Now there are many ways to interpret house burnings, and there is not the space here to set out again all the arguments for scale and motivation (see Tasić et al. 2015:1077–1079). Suffice it to say that they could be seen as one symptom of changing times and increased inter-communal tensions and aggression. We have already suggested that it seems insufficient to ascribe all putative tensions to the activities of the autonomous late Vinča household, as communal dimensions still seem paramount, for example in contexts like Stubline, though we note the appearance of larger houses in some contexts such as Banjica (Tripković 2007).

The situation remains unclear, which the timings given in this paper underline. There are probable tensions, and these and perhaps other factors not yet defined, or a combination of these possibilities, appear to have brought the Vinča network and its associated ways of living to an end. Continuing the theme of tracking the Vinča and Danubian worlds in parallel, the end of the Danubian world was probably staggered across the end of the Vinča network. As with beginnings in the Vinča A phase, we still badly need a much longer list of well-dated late Vinča sites, in order to unpick the sequence and tempo of endings. Another puzzle remains. If the Vinča phenomenon unravelled because of internal tensions (however constituted), this does not seem to have been accompanied by the same kind of material regionalisation as seen for example in the late LBK (e.g., Pechtl 2015). Some regionalisation is apparent, and this paper has followed the categorisation of the Turdaş culture in Transylvania as distinct from late Vinča culture (Drăsovean 1996.28, 93–94). But material culture including ceramics in the Vinča D phase does not appear to project the kind of much tighter regional groupings, perhaps reflective of increasing concern for local identities and interests, which seem to characterise the end of the LBK. We note again, however, the date estimates for a greater overlap between Vinča C and Vinča D ceramics than was apparent with earlier phases, and perhaps this greater variability could be an important clue to follow further at a variety of regional and local scales.

---

Fig. 41. Earliest Vinča A ceramics (cf. Fig. 25) in comparison to various readings of the dating of the LBK diaspora (cf. Jakucs et al. 2016.Fig 24).
Conclusions and questions for future research

We conclude that this study indicates much more complex circumstances for the appearance of the Vinča phenomenon than envisaged in most previous approaches; that it sketches a steadily intensifying network, which reached its peak of connectivity already in the Vinča B2 phase, which was maintained through the Vinča C phase and even into the Vinča D phase, though there are some signs of regionalisation in that late phase; and that Vinča ceramics remained relatively stable in the Vinča D phase, even though this is a time widely characterised by many researchers as one of tensions and even crisis. We have used the term network in preference to that of culture; the nature of the network is compatible with widely shared practices and perhaps beliefs, but connectivity rather than exclusivity is characteristic, and sharp boundaries are not apparent.

Although these conclusions help to redefine the nature of the Vinča phenomenon, our study has raised at least as many questions as answers. In particular, it has highlighted a long list of questions about the circumstances of beginnings and endings, but there are also plenty of unresolved aspects of the long, middle part of the sequence. To answer such questions in future research, a series of challenges need to be met. The typology of Vinča ceramics could be much further refined (with no disrespect intended towards the long list of heroic pioneers and predecessors in this fundamentally important field). Correspondence analysis of the bowls in the upper portion of the Vinča-Belo Brdo stratigraphy needs to be completed, and comparable exercises could be carried out on other key assemblages across the distribution of the network. More sites should and could be radiocarbon dated, using short-life samples of known taphonomy from definable contexts, to avoid age-offsets. All these tasks are feasible, and exploitation of existing archives (as shown in the study of Vinča-Belo Brdo: Tasić et alii 2016a) is at least as important as the application of best practice in new excavations. The scale of new dating, if within a refined system of typology and seriations, need not be massive to be effective. There is every reason to be optimistic that further refinements to the chronology of the Vinča potscape, down to the precision of lifetimes and generations, can realistically be achieved in the next generation or two of research.

\(^{19}\) Additionally, five thermoluminescence (TL) ages are reported on sherds from Feature 121 at Divostin II by McPherron and Srejović (1988. Ch. 4). These measurements were made using the fine-grain technique (Zimmerman 1971), although no checks were made for anomalous fading (Wintle 1973) nor radon escape (Desai, Aitken 1974). Given the provisional nature of these measurements, no error is quoted for the measurements on each sherd and so they cannot be included in the modelling presented here. Similarly, no error is reported for the average magnetic inclination and declination measurements made from samples from Houses 14, 15, and 16 at Divostin II, two houses from Grivac, and the middle of the Vinča layer at Gomolava, which are also reported by McPherron and Srejović (1988. Ch. 4). Again, this prevents these measurements from being calibrated and included in the chronological models.
Tab. 2. Radiocarbon determinations and related stable isotopic measurements for samples associated with Vinča ceramics (all stable isotope measurements were made using Isotope Ratio Mass Spectrometry, except those marked * which were made by Accelerator Mass Spectrometry).
