Mental health and well-being during the COVID-19 pandemic: longitudinal analyses of adults in the UK COVID-19 Mental Health & Wellbeing study

Background
The effects of coronavirus disease 2019 (COVID-19) on mental health and well-being are likely to be profound and long-lasting and will extend beyond those who have been directly affected by the virus. However, it is unclear who will be affected and to what extent such effects will generalise across all aspects of mental health.

Evidence from previous public health epidemics (for example the severe acute respiratory syndrome (SARS) virus) illustrated that the adverse effects are more common in some groups and that the detrimental effects are more pronounced among certain aspects of mental health than others. Increased risk of suicide was evident following SARS in older adults. Cross-sectional and longitudinal evidence (over 4 weeks) from China during the early stages of the outbreak of COVID-19 found high levels of mental health problems and distress in the general population. A study from Spain reported that distress during lockdown was associated with younger age and being female. Data from the University College London COVID-19 Social Study, which started post-pandemic, suggests self-harm and thoughts of suicide/self-harm were higher among women, Black, Asian and minority ethnic groups, people experiencing socioeconomic disadvantage and those with mental disorders. Repeated cross-sectional and longitudinal analysis of individual responses to the UK Household Longitudinal Study panel, including pre-pandemic data, have also demonstrated that mental health deteriorated in the early stages of the pandemic. All of these studies point to elevated rates of anxiety, depression, stress, suicide risk and post-traumatic stress in the initial stages of the pandemic.

On the 23 March 2020, a nationwide lockdown was announced by the UK government with the public instructed to stay at home, socially distance and self-isolate with strict guidance about movement outside of one’s household. Public health measures are important to protect physical health, but it is essential that we gain a clearer understanding of the mental health and well-being of the UK population during the COVID-19 pandemic. Such understanding is vital to ensure that those affected receive the support that they require and to enable us to be better prepared for a potential second wave of the pandemic and for future outbreaks. Lockdown and the social and economic consequences of COVID-19 are likely to be associated with loneliness, social isolation and entrapment. To track their effects longitudinally, we assessed a wide range of mental health and well-being outcomes including: symptoms of depression and anxiety; well-being; defeat; entrapment; suicidal thoughts and behaviours; and loneliness.

Aims
The current study investigates the mental health and well-being of adults in the UK in the early weeks of the COVID-19 pandemic. Using a quota survey design and a sampling frame that permitted recruitment of a national sample, we report the mental health and

Conclusions
The mental health and well-being of the UK adult population appears to have been affected in the initial phase of the COVID-19 pandemic. The increasing rates of suicidal thoughts across waves, especially among young adults, are concerning.
well-being of adults in the UK at three time points across 6 weeks following the COVID-19 lockdown in the UK. We also investigated whether outcomes varied by sociodemographic characteristics and those with pre-existing mental health problems, given their established vulnerability.\textsuperscript{1,16,17}

**Method**

**Study design, setting and participant recruitment**

Participant recruitment was conducted by Taylor McKenzie, a social research company. We recruited a non-probability sample of adults (aged 18 years or older) from across the UK to the UK COVID-19 Mental Health & Wellbeing study (UK COVID-MH), with a longitudinal study design. We employed a quota sampling methodology, with quotas based on age (18–24 years: 12%; 25–34: 17%; 35–44: 18%; 45–54: 18%; 55–64: 15%; ≥65: 20%), gender (women: 51%; men: 49%), socioeconomic grouping (SEG: AB: 27%; C1: 28%; C2: 20%; DE: 25%, based on occupation, where A, B and C1 are higher and categories C2, D, E are lower) and region of the UK (12 regions). The weighted and unweighted participant characteristics are presented in Table 1, with further details of gender identity and region reported in supplementary Tables 1 and 2. Weights are based on National Readership Survey and Office for National Statistics data for SEG and UK region, respectively and Census data for age and gender.\textsuperscript{18,19} Given the time sensitive nature of the study, a quota methodology was selected over probability sampling because it facilitated the recruitment of a well-stratified UK sample at the early phase of lockdown. Moreover, given the constraints of lockdown, online recruitment was the only feasible design.

Between 31 March and 9 April 2020, members of an existing online UK panel (Panelbase.net) were invited by email to take part in an online survey on health and well-being (wave 1). The panel has approximately 300 000 registered adult members. In total, 7471 panel members were invited to take part, 3077 were included in the final sample (target sample was n = 3000) and 4394 did not take part in the survey. The majority were screened out as a particular quota was full (n = 3527) and the remainder dropped out (n = 867; see Methods in the supplementary materials; available at https://doi.org/10.1192/bjp.2020.212). Respondents were asked demographic questions to determine whether they qualified for the study and if they did, they were re-directed to the survey.

After providing informed consent online, participants completed a wide range of psychological and social measures including questions about COVID-19. Only findings related to depression, anxiety, suicidal and self-harm history, defeat, entrapment, loneliness and well-being are reported here. Participants were informed that they would have the opportunity to participate in a minimum of six waves of the survey that would track the health and well-being of the UK during the current COVID-19 outbreak. All those who took part in wave 1 were invited to take part in the follow-up waves, and missing wave 2 did not exclude participation in wave 3. The follow-up surveys were scheduled to ensure a minimum of 1 week (wave 2) and 3 weeks (wave 3) between each participant completing a wave.

Three additional waves were scheduled between end of May and autumn 2020, with longer-term follow-ups also anticipated. This data collection schedule was decided to minimise fatigue effects and to maximise follow-up over time. In addition, we anticipated that after the initial shock of lockdown, changes in participants’ well-being may be less marked over time thereby not requiring weekly data collection. Findings for waves 1 (31 March to 9 April 2020), 2 (10 April to 27 April 2020) and 3 (28 April to 11 May 2020) are reported here. At wave 2, 89% (n = 2742) completed the survey and at wave 3 the survey was completed by 85% (n = 2604; see Fig. 1 for flow chart of participants across the waves).

The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008. All procedures involving human patients were approved by the University of Glasgow’s Medical, Veterinary & Life Sciences Ethics Committee (approval number: 200190146). The study was pre-registered at aspredected.org (#41910). Participants received £1.50 for the completion of the surveys and were entered into prize draws. A list of mental health support organisations was made available to participants online.

**Measures**

Suicidal history was assessed via two items adapted from the Adult Psychiatric Morbidity Survey.\textsuperscript{20} Have you ever made an attempt to take your life, e.g. by taking an overdose of tablets or in some other way? (yes/no) (suicide attempt history) and Have you ever deliberately harmed yourself in any way but not with the intention of taking your life, e.g. by taking an overdose of tablets or in some other way? (yes/no) (self-harm history). If respondents answered yes to the suicide attempt or the self-harm history questions, they were asked ‘when was the last time you deliberately harmed yourself?’ (past week, past month, past 6 months, more than 6 months, more than 12 months). We report self-harm and suicide attempts in the past week. Suicidal ideation in the past week was assessed by the question ‘How often have you thought about taking your life in the last week?’ (‘one day’, ‘several days’,

\( \textsuperscript{a} n = 3073. \)

\( \textsuperscript{b} n = 3569. \)

\( \textsuperscript{c} \) Categories A,B,C1, high socioeconomic group; categories C2, D, E low socioeconomic group.
Depressive symptoms were assessed via the nine-item Patient Health Questionnaire (PHQ-9\textsuperscript{21}). The 7-item Generalized Anxiety Disorder (GAD-7)\textsuperscript{22} tool was used to assess symptoms of generalised anxiety disorder. Both measures ask how often symptoms are bothering the respondents in the past 2 weeks. Scores of $\geq 10$ on both measures are thought to indicate moderate levels of depression and anxiety and are used as cut-off points here.\textsuperscript{22,23}

Feelings of defeat (perceived failed struggle and loss of rank) were assessed using four items from Griffiths’ short-form scale.\textsuperscript{24} The Entrapment Scale Short-form\textsuperscript{25} was used to explore perceptions of entrapment (feeling trapped by thoughts and feelings or situation). Mental well-being was assessed via the 7-item Short Warwick Edinburgh Mental Well-Being Scale (SWEMWBS).\textsuperscript{26} Loneliness was assessed using the UCLA 3-item scale.\textsuperscript{27} The National Readership Survey social grade\textsuperscript{18} was used as an indicator of socioeconomic group (SEG): high (A + B + C1) versus low (C2 + D + E).

To assess pre-existing mental health conditions, participants were first asked if they had any long-standing physical or mental impairment, illness or disability. Participants were then asked to select their mental or physical impairment from a list of options, which included mental health conditions, neuro-divergent disorders and alcohol and drug problems, and these responses were used to create a dichotomous variable for presence or absence of a pre-existing mental health condition (see Table 2 of the Methods in the supplementary materials).

Statistical analysis
All analyses were conducted using Stata MP 16. Our analyses were conducted using an imputed data-set of the 3077 participants who completed the survey at wave 1 as there were significant differences in the mental health of those who did and did not complete all waves of the survey. We used multiple imputation (MI) to generate 50 data-sets for each outcome variable. MI generalised estimating models (MI-GEE) were then constructed to test the changes in the variables across waves for the whole sample. This approach is suitable for longitudinal data.\textsuperscript{28,29} As a sensitivity check, we ran all analyses with and without MI and found a similar pattern for both analyses. The GEE results presented here are those using MI. GEE models use a multilevel approach and produce odds ratios (ORs).

For the binary outcome variables (suicidal ideation, PHQ-9 and GAD-7 cut-off scores) binomial logit modelling was used, and for the continuous outcome variables (defeat, entrapment, loneliness, and positive well-being) linear Gaussian identity modelling was used. Region (South England, English Midlands, North England, Scotland, Wales and Northern Ireland) was controlled for in all analyses. We modelled the temporal covariation using an unstructured correlation matrix, as the pattern of associations was neither fully exchangeable nor had an first-order autoregressive structure. Further GEE models were conducted to test for subgroup differences in the outcome variables: as a function of age (18–29, 30–59, $\geq 60$ years), gender (men, women), ethnicity (categorised into White and minority ethnic group because of small numbers), SEG (higher, lower) and the presence of a pre-existing mental health problem (no, yes).

Additionally, interactions between each of these subgroups and changes in each outcome over the waves was also tested, with only significant interactions reported in the results. As before, the binary variables were analysed using binomial logit GEE models and the continuous variables were explored using linear Gaussian identity GEE models.

Given the large number of analyses, a false discovery rate (FDR) was applied to all the between, within and interaction $P$-values from all analyses. FDR is a method of understanding the rate of type I errors in null hypothesis testing when conducting multiple comparisons. FDR-controlling procedures are designed to control the expected proportion of ‘discoveries’ that are false.\textsuperscript{30} There were few missing data at wave 1; a small number of participants indicated that they ‘would rather not say’ for the suicidal ideation ($n = 93, 3\%$ at wave 1; $n = 91, 3.3\%$ at wave 2; $n = 71, 2.7\%$ at wave 3), suicide attempts ($n = 71, 2.3\%$ at wave 1; $n = 36, 1.3\%$ at wave 2; $n = 32, 1.2\%$ at wave 3) or self-harm ($n = 64, 2.1\%$ at wave 1; $n = 39, 1.4\%$ at wave 2; $n = 33, 1.3\%$ at wave 3) questions; these were imputed via MI. As the rates of self-harm and suicide attempts in the past week were found to be low, no inferential statistics were applied to these data.

Results

Participant characteristics
A total of 3077 adults completed the survey at wave 1 (see Table 1, Fig. 1). In the unweighted data at wave 1, 55.1% of the participants were women and 90.5% were White. Regarding age, 27.5% were aged 18–29 years, 53.2% aged 30–59 and 19.3% aged $\geq 60$ years. In total, 59.6% were married/living with partner and 92.0% self-identified as heterosexual. Over half (57.1%) reported occupations that were classified as higher SEG and 59.6% reported owning their own home (including with mortgage). Just over a quarter (27.2%) of the participants reported having a pre-existing mental health problem at wave 1 (see Table S6 in the supplementary materials).

Mental health outcomes across waves for all adults
Rates of suicidal ideation increased over time (see Table 2), with respondents at wave 2 (9.2%; OR $= 1.17$, 95% CI 1.01–1.34, $P = 0.031$) and wave 3 (9.8%; OR $= 1.24$, 95% CI 1.07–1.44, $P = 0.005$) reporting higher levels than at wave 1 (8.2%). The difference between waves 2 and 3 was not statistically significant.
The rates of suicide attempt (0.1% at wave 1, 0.7% at wave 3) and self-harm (0.7% at wave 1 and 1.4% at wave 3) in the past week were low.

A total of 21% of the participants was above the cut-off point for moderate or severe levels of symptoms of anxiety at wave 1. However, these symptoms decreased across waves, with wave 2 (18.6%; OR = 0.89, 95% CI 0.81–0.97, P = 0.012) and wave 3 (16.8%; OR = 0.82, 95% CI 0.74–0.90, P < 0.0001) being lower than wave 1 (21%); the differences between wave 2 and wave 3 was not significant. More than a quarter (26.1%) scored above the cut-off for moderate or severe levels of depression; there was no significant change across the waves.

Feelings of defeat decreased from wave 1 (mean 4.11) to wave 2 (mean 4.02; OR = 0.84, 95% CI 0.75–0.95, P = 0.003) and from wave 1 to wave 3 (mean 3.92; OR = 0.80, 95% CI 0.71–0.91, P < 0.0001; Table 2). There was no difference between waves 2 and 3. Entrapment also decreased over time, from wave 1 (mean 3.96) to wave 2 (mean 3.78; OR = 0.88, 95% CI 0.79–1.00, P = 0.04) and from wave 1 to wave 3 (mean 3.60; OR = 0.79, 95% CI 0.69–0.91, P = 0.001) but not between waves 2 and 3. Positive well-being increased from wave 1 (mean 22.27) to wave 2 (mean 22.64; OR = 1.30, 95% CI 1.09–1.58, P = 0.005) and from wave 1 to wave 3 (mean 22.92; OR = 1.58, 95% CI 1.29–1.92, P < 0.0001), but not from wave 2 to wave 3. Levels of loneliness did not significantly change over waves.

### Mental health outcomes across wave by sociodemographic characteristics and pre-existing mental health condition

Percentages and means from wave 1 have been used to illustrate differences between subgroups, although data from all waves were used in this analysis and are included in the supplementary material (see supplementary Tables 3–8).

#### Suicidal ideation

Men and women reported similar levels of suicidal ideation (see supplementary Table 3). Compared with younger adults (18–29 year olds; wave 1 12.5%) those aged 30–59 years (8.4%; OR = 0.65, 95% CI 0.49–0.85, P = 0.002) and ≥60 years (1.9%; OR = 0.14, 95% CI 0.08–0.27, P < 0.0001) reported lower levels of suicidal ideation, and those aged 30–59 were more likely to report suicidal ideation than ≥60-year-olds (OR = 4.51, 95% CI 2.43–8.39, P < 0.0001). There were no clear differences when comparing ethnic minorities to the White ethnic group (see supplementary Table 4). Those from the lower SEG were more likely to experience suicidal ideation (10.3%; OR = 1.63, 95% CI 1.24–2.10, P < 0.0001) compared with those in the higher SEG (6.6%; see supplementary Table 5). Those with a pre-existing mental health condition were more likely to experience suicidal ideation (19.3%; OR = 5.56, 95% CI 4.23–7.31, P < 0.0001) compared with those without (4.1%; see supplementary Table 6).

#### Depressive symptoms

Men reported lower levels of depressive symptoms (17.6%) than women (33%; OR = 0.44, 95% CI 0.37–0.52, P < 0.0001; see supplementary Table 3). Those who were aged 30–59 years (26%; OR = 0.55, 95% CI 0.46–0.66, P < 0.0001) and aged ≥60 years (8.2%; OR = 0.14, 95% CI 0.10–0.20, P < 0.0001) reported lower levels of depressive symptoms than younger adults (38.8%; 18–29 years), and those aged 30–59 years reported higher rates of depressive symptoms than those ≥60 (OR = 3.85, 95% CI 2.82–5.27, P < 0.0001). There were no significant differences by ethnicity. The respondents in the lower SEG were more likely to report higher levels of depressive symptoms (30.4%; OR = 1.47,
People with a pre-existing mental health condition were significantly more likely to report higher levels of depressive symptoms (54.2%; OR = 6.50, 95% CI 5.45–7.77, P < 0.0001) compared with those without (15.3%). The interaction between pre-existing mental health condition and wave was statistically significant (OR = 0.87, 95% CI 0.79–0.96, P = 0.007), with those who had a pre-existing mental health condition reporting reductions in depressive symptoms over time at both wave 2 (reduction 5.6%; OR = 0.80, 95% CI 0.67–0.96, P = 0.017) and wave 3 (reduction 7.5%; OR = 0.76, 95% CI 0.63–0.94, P < 0.009), but not from wave 2 to wave 3 (reduction 1.9%). Those with no pre-existing mental health conditions did not change over time.

Anxiety symptoms
Across the three waves, those aged 30–59 years (21.5%; OR = 0.63, 95% CI 0.52–0.76, P < 0.0001) and those aged ≥60 (6.4%; OR = 0.16, 95% CI 0.11–0.23, P < 0.0001) were less likely to score above the cut-off for anxiety symptoms compared with those aged 18–29 years (30.1%), and those age 30–59 years were more likely to be above the cut-off for anxiety symptoms than those ≥60 (OR = 3.95, 95% CI 2.79–5.61, P < 0.0001; supplementary Table 3). Men were also less likely to meet the cut-off threshold (13%) compared with women (27.5%; OR = 0.40, 95% CI 0.33–0.48, P < 0.0001). Levels of anxiety did not vary by ethnicity. Those who were of a lower SEG were more likely to score above the cut-off for anxiety symptoms (24.9%; OR = 1.49, 95% CI 1.25–1.78, P < 0.0001) compared with those in the higher SEG (18%). Participants with a pre-existing mental health condition were more likely to score above the cut-off (44.6%; OR = 5.97, 95% CI 4.95–7.19, P < 0.0001) than those with no mental health condition (11.9%; supplementary Table 6).

Defeat
Compared with those aged 18–29 years (mean 5.27), participants aged 30–59 years (mean 4.38; OR = 0.40, 95% CI 0.29–0.55, P < 0.0001) and those aged ≥60 (mean 2.45; OR = 0.06, 95% CI 0.04–0.09, P < 0.0001) reported lower levels of defeat, and 30–59 year olds scored higher than those aged ≥60 years (OR = 6.77, 95% CI 4.72–9.71, P < 0.0001; supplementary Table 7). Men reported significantly lower levels of defeat than females (OR = 0.22, 95% CI 0.17–0.29, P < 0.0001). No differences were found by ethnicity on levels of defeat. Participants from a lower SEG reported higher levels of defeat (mean 4.81; OR = 2.69, 95% CI 2.03–3.56, P < 0.0001) compared with those of a higher SEG (mean 3.83; see supplementary Table 8). Participants who reported a pre-existing mental health condition reported higher levels of defeat (mean 7.06; OR = 48.47, 95% CI 36.56–64.27, P < 0.0001) compared with those without a mental health condition (mean 3.17; see supplementary Table 8).

Entrapment
Men reported lower levels of entrapment (mean 3.14) than women (mean 4.62; OR = 0.23, 95% CI 0.17–0.31, P < 0.0001). Levels of entrapment differed significantly by age group, with those aged 30–59 years (mean 4.1; OR = 0.37, 95% CI 0.26–0.53, P < 0.0001) and those aged ≥60 years (mean 1.93; OR = 0.05, 95% CI 0.03–0.07, P < 0.0001) reporting lower levels of entrapment than those aged 18–29 years (mean 5.07), and those aged 30–59 years were higher than those aged ≥60 (OR = 8.30, 95% CI 5.58–12.34, P < 0.0001). No significant differences by ethnicity were found. Those from a lower SEG reported significantly higher levels of entrapment (mean 4.47; OR = 2.48, 95% CI 1.82–3.38, P < 0.0001) than those in the higher SEG group (mean 3.57). Participants with a pre-existing mental health condition reported higher levels of entrapment (mean 7.0; OR = 66.78, 95% CI 48.99–91.04, P < 0.0001) than those without (mean 2.79). The interaction between mental health condition and entrapment over the waves was significant (OR = 0.84, 95% CI 0.72–0.98, P = 0.02), with those who had a mental health condition experiencing a more pronounced reduction in the average entrapment score from wave 1 to wave 3 (reduction 0.63; OR = 0.70, 95% CI 0.52–0.95, P = 0.02) compared with those with no mental health condition (reduction 0.2).

Discussion

Main findings and comparison with findings from other studies
This study offers a detailed examination of the mental health and well-being of the UK adult population during the first 6 weeks of
the COVID-19 pandemic. Across every indicator, individuals from more socially disadvantaged backgrounds and those with pre-existing mental health problems report the worst mental health outcomes. The rates of suicidal ideation increased during the initial weeks of lockdown, with one in seven (14%) young adults reporting suicidal thoughts in the last week at wave 3. It is not possible to make direct comparisons with pre-COVID-19 rates, but the rate of suicidal ideation among young adults reported here (between 12.5% and 14.4% across waves) is higher than the 11% past-year suicidal ideation rate reported by young adults in another pre-COVID-19 study. The weekly suicidal ideation rates for the whole sample (9.8% at wave 3) are also higher than those reported elsewhere, with 2.8% reporting suicidal thoughts in one national study of adults.26

Across all three waves, approximately one in four respondents (wave 1 = 26.1%, wave 2 = 24.3% and wave 3 = 23.7%) experienced moderate to severe levels of depressive symptoms on the PHQ-9. This finding is concerning when compared with other pre-COVID-19 general population studies where, for example, 5.6% scored above the standard ≥10 cut-off.33 However, we urge caution when extrapolating from the PHQ-9 data to general population lockdown estimates, as a recent meta-analysis concluded that the PHQ-9 may more than double the estimate of depression compared with a structured clinical interview (using the Structured Clinical Interview for Diagnostic and Statistical Manual of Mental Disorders). Also, although we have recruited a well-stratified national sample from across the UK, quota sampling does not guarantee the same level of representativeness as probability sampling accordingly. However, it is also worth noting that our depressive symptoms findings are quite similar to the latest Office for National Statistics data for the UK adult population collected in June 2020, where 19.2% of adults reported moderate to severe levels of depression, compared with 23.7% at wave 3 in our study at the end of April/start of May 2020.

For anxiety, one in five (21%) respondents in the present sample scored above the cut-off on the GAD-7, corresponding to moderate to severe levels of anxiety at wave 1, with this rate decreasing to 16.8% by wave 3. We do not have pre-COVID-19 figures to make like-for-like comparisons; nonetheless, these rates were much higher than the established general population norms (of approximately 5%).36 Levels of mental well-being among women across all waves were lower than the general population norms for the SWEMWBS, but levels for men were similar.36

**Implications**

As already noted, the mental health of women, of young people (18–29 years), of those from more socially disadvantaged backgrounds, and of those with pre-existing mental health problems has been particularly affected during the pandemic. These groups need to be prioritised to ensure that they receive the support they require and accessible and remote clinical services tailored, as necessary, to meet this need. The trajectories across the three waves illustrate the importance of assessing different indicators of mental health and well-being. Whereas symptoms of anxiety, and levels of defeat and entrapment decreased across the three waves, depressive symptoms and loneliness remained stable but adversely affected. The findings also highlight that loneliness may become more of an issue for older adults as the pandemic unfolds, as well as for those from more socially disadvantaged backgrounds.

Across all of the analyses the mental health outcomes for those from ethnic minority and White backgrounds were similar. Despite our sample being well-stratified nationally, our sample size precludes a more fine-grained analysis of the mental health outcomes of people from specific ethnic minority communities. Such an analysis, that also takes account of intersectionality, is urgently required. The trajectories of suicidal thoughts highlight that we need to be vigilant. Although an increase in suicide is not inevitable, the present data may be an early indicator of emerging risk, especially as the economic fallout of COVID-19 escalates. The proportions of respondents reporting at least 1 day in the previous week that they wanted to end their life increased across the three waves of the study, from 8.2%, to 9.2% and 9.8% at waves 1, 2 and 3, respectively.

Given its well established relationship with suicide risk, it is surprising that levels of entrapment decreased while suicidal thoughts increased. This may reflect a lagged effect or it may be that the items assessing entrapment or depression focus on the past whereas the suicidal question is tapping uncertainty or concerns about the future. This may also explain why the positive well-being measure increased, as it also focuses on the past, and likely increased as levels of anxiety decreased. The focus on future orientation is potentially crucial as future thinking is a recognised cognitive factor associated with suicidal ideation independent of depression. Indeed, inspection of the items to assess depressive symptoms illustrates this point as they are tapping the extent to which respondents are ‘bothered’ by problems in the recent past; so after the initial shock of lockdown, one’s appraisal of these problems is relatively stable in the short term. By contrast, in the early weeks of the pandemic, the anticipated impact of the economic and social disruption to come may have exacerbated one’s feelings of hopelessness and suicidal ideation and hence explain the increase in the latter.

Survey-based research needs to be supplemented with qualitative interviews to determine whether our conjecture about the cause of increasing levels of suicidal ideation is supported. By way of post hoc analyses, we also inspected the responses to the suicidal question in the PHQ-9 (“Thoughts that you would be better off dead, or of hurting yourself in some way?”) and we find a similar pattern as above, of increasing suicidal thoughts. It is essential, therefore, that suicidal thoughts continue to be tracked as we emerge from lockdown and navigate national/local restrictions. These data are also consistent with the recent report from the National Child Mortality Database that points to a potential increase in child suicide deaths in the early stages of the pandemic. The defeat and entrapment levels are also of concern, especially among young adults at wave 1. At wave 1, more than a third (37%) of young people scored above the recommended cut-off (>5) for entrapment, which indicates that further screening for suicide ideation is warranted.25

**Limitations**

Indicators of mental health were based on self-reports rather than clinical diagnoses, as a result, we can only comment on the trajectory of the symptoms of mental ill health rather than psychiatric disorder. Despite successfully recruiting a quota-based national sample, similar to all studies that recruit via digital means, our sample is likely to underestimate the mental health effects of COVID-19 as those who are digitally excluded may be underrepresented. Also, those who did not complete all waves tended to have worse mental health at wave 1. Future research is required to understand what aspects of the pandemic and the pandemic response may have contributed to negative mental health outcomes as well as those factors and activities that may be protective.

To conclude, the mental health and well-being of the UK adult population appears to have been affected in the initial phase of the COVID-19 pandemic, particularly women, young adults, the socially disadvantaged and those with pre-existing mental health
problems. The trajectory of increasing rates of suicidal thoughts, especially among young adults, is particularly concerning. These early data highlight that detailed monitoring of longer-term mental health outcomes and inequalities is essential.

Data availability

The data that support the findings of this study are available from the corresponding author (R.C.O’C.), upon reasonable request.

Author contributions

R.C.O’C., K.A.R., K.W. and S.C. had the idea for the study and R.C.O’C. secured funding for the study. All authors contributed to the study design. K.W. and E.F. led the statistical analyses alongside S.C. R.C.O’C. led the drafting of the manuscript but all authors contributed to the drafting and approved the final manuscript for submission.

Funding

University of Glasgow, Samartans, Scottish Association for Mental Health and the Mindstep Foundation.

Declaration of interest

R.C.O’C. reports grants from Samaritans, grants from Scottish Association for Mental Health, grants from Mindstep Foundation, during the conduct of the study; grants from National Institute for Health Research, grants from Medical Research Foundation, grants from Scottish Government, grants from NHS Health Scotland/Public Health Scotland, outside the submitted work; and he is co-chair of the Academic Advisory Group to the Scottish Government’s National Suicide Prevention Leadership Group. He is also a member of the National Institute for Health and Care Excellence’s guidance development group for their new self-harm guidelines. C.L.N. reports grants from Medical Research Council, during the conduct of the study. S.P. reports personal fees from Health Service Executive, Dublin, Ireland; personal fees from NHS Health Scotland, Edinburgh, Scotland; outside the submitted work. T.F. reports grants from the Scottish Government Scotland National Suicide Prevention Leadership Group, during the conduct of the study. Outside the submitted work, reports grants from NHS Scotland Endowment Fund; and is a co-chair of the Early Career Group of the International Association for Suicide Prevention. E. F. reports grants from Pfizer Limited and Versus Arthritis, grants from Versus Arthritis, grants from Football Association, grants from Medical Research Foundation, grants from U. S. Army Medical Research and Materiel Command, outside the submitted work. E.S. (Samartans) and B.W. (Scottish Association for Mental Health) are employees of two of the funders of this research. K.W., S.C., D.B.O’C. and K.A.R. have nothing to disclose.

Epidemics: the first pandemic – the Justinianic Plague (541–549)

Greg Wilkinson

The Early Medieval Pandemic began in 541 with the Justinianic Plague (Yersinia pestis) and continued through the 8th century. Today, echoes sound from the accounts of Procopius (c. 500 to after 565), Evagrius Scholasticus (born c. 536) and John of Ephesus (c. 507–588).

The historian Procopius says that pestilence embraced the entire world and blighted the lives of all men, respecting neither gender nor age, attacking at all times of the year, starting in Egypt, then to Palestine and on to the land of the Persians and barbarians (Dewing 1914). There was sudden fever, and within days a bubonic swelling developed in the groin or elsewhere. Some became comatose, forgot those familiar to them and seemed to be sleeping. If anyone cared for them, they would eat without waking; but some were neglected, and they died through lack of sustenance. Others developed delirium, with insomnia and distorted imagination: they suspected men were coming to destroy them, and would rush off in flight, crying out. Those attending them often got infected and died as well.

Evagrius, scholar and intellectual, describes being seized with buboes while still a schoolboy, and losing by recurrence of the plague at different times his wife, several children, many kin, as well as domestic and country servants; not quite 2 years before, his wife and several children, many kin, as well as domestic and country servants, died, soon after his mother. He was living in Constantinople when the scourge fell: John was living in Constantinople when the scourge fell: an agonizing event for many.

John of Ephesus was a Byzantine historian. Much of his Ecclesiastical History is missing but part appears in the Chronicle of patriarch Michael the Syrian (1126–1199) (Chabot 1899). John was living in Constantinople when the scourge fell: ‘men became enraged, like dogs, went mad, attacked each other, went into the mountains and committed suicide’. It raged among the poor; there were days when 5000 were carried away, others 7000, others 12,000, and up to 16,000 in one day; over 300,000 were taken from public places. When those of low rank were dead, the devastator stretched out his hand over the mighty, not forgetting animals and reptiles.
