## ABSTRACT

The Cerrado is the most diverse tropical savanna in the world. As a fire-prone ecosystem, natural fire in the Cerrado shapes plant communities and drives evolutionary processes. Human activities and landscape management can alter natural fire regimes and reshape Cerrado dynamics, making biodiversity conservation a challenge, particularly in densely populated areas. We reconstructed the historical fire regime of three protected areas (PA) and their buffer zones in São Paulo state to understand how current fire exclusion policies are affecting fire regimes and to measure how human-climate-fire relationships can change in areas under different land management. We used Landsat satellite imagery, from 1984 to 2017, with 30 meters of spatial resolution and 16 days of temporal resolution. In total, we mapped 49,471 hectares of burned area, and we detected variations in fire frequency and fire size among sites. PA dominated by open savanna in Itirapina concentrated 93% of all observed fires, while PA dominated by forest-like formations in Assis represented only 2% of the fires. Annual rainfall showed a very weak relationship ( $R^2 = 0.04$ ) with annual total burned area, while the rainfall split between dry and wet seasons showed a tendency to have a fuel moisture effect which determined the vegetation available to burn in the dry season ( $R^2 = 0.09$ ). Fire regimes in PA were similar to those observed in buffer zones suggesting that fire-exclusion policies do not effectively prevent fires in PA that are surrounded by an anthropic matrix where fire is often used. When we included human factors in addition to rainfall, our models explained 44% of variation of burned areas. We conclude that fire regimes in São Paulo Cerrado have been modified by humans and that fire exclusion is not a suitable policy for protected areas in this fire-prone ecosystem.

**Key- words:** savannas; protected areas; anthropic landscapes; forestry; Landsat; fire management

66 **Introduction**

67 Prior to the rapid land cover conversion from natural areas to agriculture  
68 lands observed in Brazil during the last century, the Cerrado biome covered an area  
69 of ca. 2 million km<sup>2</sup>, about 25% of the Brazilian territory (Durigan & Ratter, 2016).  
70 Globally classified as a humid savanna, the Cerrado comprises a complex mosaic  
71 of vegetation types, ranging from open grasslands to forest-like formations  
72 (Coutinho, 1990; Eiten, 2001; Ribeiro & Walter, 2017). Currently, The Cerrado  
73 biome contains 13 127 known plant species (Overbeck et al., 2015), of which ca. 4  
74 400 are endemic (Klink & Moreira, 2002), and it has been considered the most  
75 diverse savanna in the world in terms of plant, avian, mammal and amphibian  
76 species (Murphy et al., 2016).

77 These characteristics have ranked the Cerrado among the global hotspots  
78 for biodiversity conservation (Myers et al., 2000). Increasing anthropogenic activities  
79 such as forestry, agriculture and livestock farming have had severe impacts on this  
80 ecosystem, representing the main threat to Cerrado conservation (Alencar et al.,  
81 2020). Still, only 7% of its total area is under legal protection in Brazil (Soares-Filho  
82 et al., 2014). In the state of São Paulo, Cerrado vegetation originally covered 14%  
83 (35 000 km<sup>2</sup>) of state's total area (Brito et al., 1997), but the currently remaining 8  
84 353 fragments represent only 5.7% (2 000 km<sup>2</sup>) of this original cover, with 99.5% of  
85 these composed of small patches (< 4 km<sup>2</sup>) of Cerrado vegetation within a matrix of  
86 cropland, pasture and dense urban areas (Kronka et al., 2005). Of these remnants,  
87 only 12% (~250 km<sup>2</sup> - 0.7% of original cover) are currently under protection (Fiori &  
88 Fioravanti, 2001).

89 As with other savannas, fire is one of the most important drivers of  
90 vegetation dynamics, shaping the composition, structure and function of plant  
91 communities (Coutinho, 1990; Miranda et al., 2009). This dynamic emerged around  
92 4 millions of years ago with the expansion of C<sub>4</sub> grasses and global savannas  
93 (Keeley & Rundel, 2005; Pagani et al., 1999). A natural fire regime is determined  
94 mainly by climate, where the interaction between accumulated rainfall and  
95 seasonality determine fuel build-up during the wet season and fuel moisture during  
96 the dry season (Alvarado et al., 2020; Bradstock, 2010; van der Werf et al., 2008).  
97 Before the arrival of humans, fires occurred late in the dry season or in the  
98 beginning of the rainy season, ignited mainly by lightning (Dias, 2006). However,

99 when humans began to use fire for domestic activities about ~100 000 years ago  
100 (Goldammer, 1993; Vale, 2002), they modified fire regimes, reshaping the climate-  
101 fire relationship (Bird et al., 2012). Human activities can cause landscape  
102 fragmentation, increasing fire ignitions or suppressing fire occurrence, which can  
103 also alter fire seasonality and modify the fire dynamic (Archibald, 2016; Bowman et  
104 al., 2009).

105 Tracking fire regime changes is therefore essential to the effective  
106 conservation of this threatened and fragmented vegetation. Remote sensing tools  
107 allow us to monitor more than three decades of these changes and reconstruct  
108 contemporary ecological dynamics (Lentile et al., 2006). Particularly useful are the  
109 Landsat series image products, including the Landsat 5 TM sensor, launched in  
110 1984, and the Landsat 7 ETM+ and Landsat 8 OLI sensors, which are still in  
111 operation. Landsat imagery, which offers a good compromise between spatial  
112 resolution (30 m) and moderate temporal resolution (16 days), can be used to  
113 reconstruct fire occurrence at local (Alvarado et al., 2018; Smith et al., 2007) and  
114 regional scales (INPE, 2018) and to identify burn scars over a period of more than  
115 30 years.

116 In the present study, we reconstructed 33 years of fire occurrence within  
117 and around three Cerrado protected areas in São Paulo state, Brazil. These areas  
118 share similar environmental conditions in terms of climate and vegetation type and  
119 management policies, and they are all surrounded by a complex landscape  
120 characterized by severe land cover changes. Moreover, the same institution has  
121 managed these areas and applied a fire exclusion policy since the 1980s. Given  
122 that, we hypothesized that because this fire exclusion policy was equally applied to  
123 all areas, no differences in fire regime should be observed between them. We thus  
124 aimed to answer the following questions: i) Are there differences in fire regime  
125 among protected areas under the same environmental and management  
126 conditions? ii) Are these differences, if existent, driven primarily by climate  
127 conditions or by human activities?

128

## 129 **Methods**

### 130 *Study sites*

131 This study covered three protected areas in São Paulo state, Brazil,  
 132 comprising natural ecosystems and silvicultural stands enclosed within areas of  
 133 public land under varying protection status, which are surrounded by private rural  
 134 and/or urban lands. To quantify the influence of the surrounding anthropogenic  
 135 activities on fire regimes, we delineated a buffer of 7 km around each study site,  
 136 covering in total 14 624 ha of protected areas and 78 153 ha of buffer zones (Table  
 137 1). Buffer zones comprised land uses such as sugarcane plantations, food crops  
 138 (soybean, corn, rice), pasture, forestry, industrial areas, and occasionally  
 139 unprotected remnants of native vegetation (cerradão and ecotonal zones with  
 140 seasonal tropical forest) (Figure 1). In São Paulo state, the use of fire as a  
 141 management tool was permitted until the year 2000 and was widely used to renew  
 142 pasture lands and facilitate sugarcane harvesting. Since then, legal constraints on  
 143 burning have been imposed (state law 11 241/ 2002), which has gradually reduced  
 144 the use of fire.

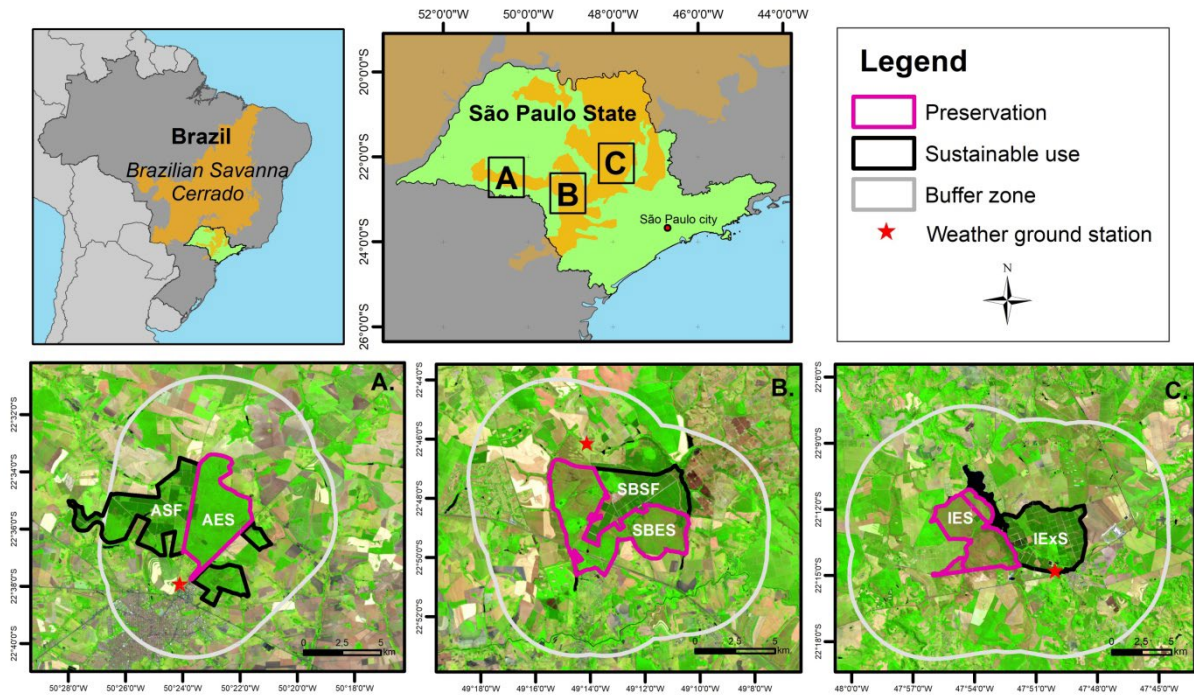

145 **Table 1.** Description of study sites; NA means information is not available.

Site	Protected area type	Conservation status	Area (ha)	% of open savanna
<b>Assis</b>	Ecological Station – AES	Full preservation since 1984	1 755	1.2
	State Forest– ASF	Sustainable use since 1959	2 672	0
	Buffer	Buffer zone	15 420	NA
<b>Santa Bárbara</b>	Ecological Station – SBES	Full preservation since 1984	2 796	49.3
	State Forest – SBSF	Sustainable use since 1964	1 593	0
	Buffer	Buffer zone	20 394	NA
<b>Itirapina</b>	Ecological Station – IES	Full preservation since 1984	2677	91.6
	Experimental Station– IExS	Sustainable use since 1957	3 131	0
	Buffer	Buffer zone	42 339	NA

147           The native vegetation remaining in the study sites represents a gradient of  
148 different Cerrado vegetation types, from open grasslands to forest-like vegetation  
149 ("cerradão"). The Assis Ecological Station (AES) is dominated by "cerradão", as it is  
150 located at a transitional area to seasonal tropical forest (E. D. S. Pinheiro &  
151 Durigan, 2009); Santa Bárbara Ecological Station (SBES) comprises open  
152 savannas and "cerradão" (Abreu et al., 2017) and Itirapina Ecological Station (IES)  
153 is mainly covered by open savannas (Zanchetta et al., 2006). Sustainable use areas  
154 are represented by the Assis State Forest (ASF), Santa Bárbara State Forest  
155 (SBSF) and Itirapina Experimental Station (IExS), all characterized by plantations of  
156 exotic species of *Pinus* and *Eucalyptus* interspersed with small patches of  
157 "cerradão" (Gurgel-Garrido et al., 1997). Management of these areas is under the  
158 purview of the São Paulo Forestry Institute (Instituto Florestal).

159           Species composition of cerrado vegetation is very similar among the three  
160 study sites. The dominant woody species in Assis are *Copaifera langsdorffii* (Desf.)  
161 Kuntze, *Protium heptaphyllum* (Aubl.) Marchand, *Ocotea corymbosa* (Meisn.) Mez,  
162 *Vochysia tucanorum* Mart., and *Stryphnodendron rotundifolium* Mart. (Pinheiro &  
163 Durigan, 2012). In Itirapina, among the dominant species are *V. tucanorum*, *Myrcia*  
164 *guianensis* (Aubl.) DC., *Myrsine umbellata* Mart., *Qualea grandiflora* Mart. and  
165 *Ocotea pulchella* Mart. (Giannotti, 1988). In Santa Bárbara, the most abundant trees  
166 are *O. corymbosa*, *C. langsdorffii*, *Miconia ligustroides* (DC.) Naudin, *M. umbellata*,  
167 and *S. rotundifolium* (Neto, 1991). Although the proportions of the dominant species  
168 vary among sites, all species mentioned above occur in the three sites, possibly due  
169 to the similarities in climate and soil properties (deep, sandy, with low fertility and  
170 low soil water holding capacity) among them.

171

172

173 **Figure 1.** Location of the study areas: **A**) Assis Ecological Station (AES), Assis State Forest  
 174 (ASF) and Assis buffer zone; **B**) Santa Bárbara Ecological Station (SBES), Santa Bárbara  
 175 State Forest (SBSF) and Santa Bárbara buffer zone; **C**) Itirapina Ecological Station (IES),  
 176 Itirapina Experimental Station (IExS) and Itirapina buffer zone. Background from Landsat 8  
 177 (OLI) satellite images, false color composition (from 2017-09; bands 6, 5, 4)  
 178

179 Annual rainfall at the studied sites ranged from 1 100 to 1 450 mm between  
 180 1985 and 2017 (Agência Nacional das Águas, ANA). Seasonality is defined by the  
 181 two characteristic seasons of tropical savanna climates: a warm and rainy season  
 182 (monthly mean temperature 22–23 °C; monthly rainfall > 100 mm) between October  
 183 and March (~80% of annual rainfall); and a cold and dry season (monthly mean  
 184 temperature 17–19 °C; monthly rainfall < 100 mm) between April and September  
 185 (~20% of annual rainfall). Demographic density in the buffer zones is estimated at  
 186 206 inhabitants/km<sup>2</sup> in Assis, 14 inhabitants/km<sup>2</sup> in Santa Bárbara and 27  
 187 inhabitants/km<sup>2</sup> in Itirapina (IBGE, 2014).

### 188 *Management history*

189 The State Forests—Assis (ASF) and Santa Bárbara (SBSF)—are protected  
 190 under both the Brazilian National Conservation System (Sistema Nacional de  
 191 Unidades de Conservação, SNUC, National Law 9985/ 2000) and environmental  
 192 state laws. These areas, as well as the Experimental Station of Itirapina (IExS),  
 193 were created in the mid-20<sup>th</sup> century to develop scientific research focused on

194 sustainable use of exotic woody species of *Pinus* and *Eucalyptus*. A fire  
195 suppression policy was adopted then to prevent economic losses caused by  
196 accidental and arson fires.

197           Conversely, Ecological Stations— Assis (AES), Santa Bárbara (SBES) and  
198 Itirapina (IES)—comprise one of the most restrictive categories of the SNUC, having  
199 a strict full protection status. These areas were created during the 1980s, when the  
200 natural cover remaining within pre-existing sustainable use areas were re-  
201 categorized to improve nature conservation. None of these areas are open to public  
202 visitation and only allow scientific research and guided environmental education.  
203 After these areas were established as protected areas, the same fire suppression  
204 policy already adopted for sustainable use areas was maintained. Since then,  
205 woody encroachment due to fire suppression has been observed in all these areas,  
206 as reported by Pinheiro & Durigan (2009) and Abreu et al. (2017) for Assis and  
207 Santa Bárbara, respectively.

#### 208 *Remote sensing data: mapping burn scars*

209           We defined the fire season for the study sites using the Active Fire product  
210 (MOD14) from the *Moderate Resolution Imaging Spectroradiometer* (MODIS)  
211 sensor onboard the TERRA satellite, covering the period 2004–2014 for São Paulo  
212 state. To delimit burn scars, we then acquired 805 multispectral surface reflectance  
213 images, from Landsat 5, 7 and 8, for the period 1985–2017 (Supplementary  
214 material S1), for path and row (WRS-2) 220/75 (Itirapina), 221/76 (Santa Bárbara)  
215 and 222/76 (Assis), from *Earth Resources Observation and Science* (EROS) Center  
216 *Science Processing Architecture* (ESPA; <https://espa.cr.usgs.gov/>). All additional  
217 spatial data were reprojected to Universal Transverse Mercator (zones 22S or 23S)  
218 using the WGS-84 reference datum to match the acquired imagery. Due to the  
219 location and size of the studied areas, burn scars mapping was not affected by the  
220 known scan line corrector mirror (SLC-off) failure of ETM+.

221

#### 222 *Rainfall data*

223           For each study site, we obtained data on monthly rainfall and observed  
224 days of rain, for the period 1984–2017, from the closer weather ground stations

225 (Figure 1) operated by the Brazilian National Water Agency (*Agência Nacional de*  
226 *Águas*, ANA, <http://www.snirh.gov.br/hidroweb>).

227

### 228 *Tree cover and land use data*

229 Land use and cover was obtained from Projeto MapBiomias - Collection 5  
230 (<https://mapbiomas.org/>). We extracted these data for the years 1985, 1995, 2005  
231 and 2019 to produce annual land cover maps (Supplementary material Fig. S2), to  
232 compare land cover changes over time for the three sites, and to show all the  
233 differences and similarities between sites. We obtained tree cover estimation for all  
234 study sites, using the Global Forest Cover Change Tree Cover Multi-Year Global  
235 30m V003 product (GFCC30TC V003), for the years 2000, 2005, 2010 and 2015 to  
236 evaluate changes in tree cover between sites and between areas with different  
237 conservation statuses over time. We characterized these differences using boxplots  
238 (Supplementary material Fig. S3). These data were provided by NASA Earth Data  
239 repository (<https://search.earthdata.nasa.gov/>).

240

### 241 *Data processing and analysis*

#### 242 *Fire season*

243 We determined the fire season by combining monthly counts of active fires  
244 for the period 2004–2014 (MOD14 - Terra) and mean monthly rainfall (from weather  
245 ground stations) for the same period. We applied a threshold of  $\geq 70$  mm to the  
246 monthly rainfall to determine the rainy (October–March) and dry seasons (April–  
247 September), and as expected, most active fires occurred during the dry season.

248

#### 249 *Fire regime reconstruction*

250 We detected and delineated every observable burn scar in all acquired Landsat  
251 images by combining the short-wave and near infrared bands, following the method pro-  
252 posed by Alvarado et al. (2017). For TM and ETM+, we created false color composi-  
253 tions using bands 5 (short-wave infrared, 0,55 - 1,75  $\mu\text{m}$ ), 4 (near infrared, 0,76 -  
254 0,90  $\mu\text{m}$ ) and 3 (visible red, 0,63 - 0,69  $\mu\text{m}$ ). For the OLI sensor, we created false  
255 color compositions using bands 6 (short-wave infrared, 1,57 - 1,65  $\mu\text{m}$ ), 5 (near in-

256 frared, 0,85 - 0,88  $\mu\text{m}$ ) and 4 (visible red, 0,64 - 0,67  $\mu\text{m}$ ). We standardized bright-  
 257 ness and contrast for all scenes of the same sensor to minimize reflectance varia-  
 258 tion and reduce observation error.

259 We then performed visual detection and manual delineation of burn scars in  
 260 every Landsat scene across each year using a standardized mapping scale of  
 261 1:10000. The resulting dataset contained information, in vector format, about the  
 262 location, area and date of observation for every burn scar. Validation was performed  
 263 by comparing our mapping results to the official fire records for each reserve. We  
 264 then converted vector data into time series of annual burned (pixel value = 1) and  
 265 non-burned (pixel value = 0) binary raster maps with 30-m pixel size, from which we  
 266 calculated the following metrics (Table 2):

267 **Table 2.** Remote sensing derived metrics used to assess fire regimes.

<b>Metric</b>	<b>Unit</b>	<b>Description</b>
Fire count	<i>freq.</i>	A map of the total number of fire events observed over the 32 years studied, obtained from the per-pixel sum of all overlapped annual burn maps.
Density of ignitions	<i>Ignitions/ha</i>	Number of burn scars observed per year divided by the total area of each studied site.
Burned area	<i>ha</i>	Sum of individual vector burn-scar sizes (in hectares) per year or per month.
Accumulated burned area	<i>ha</i>	Sum of all annual burned area maps.
Relative burned area	<i>%</i>	Proportion between total burned area and total area of each site (in %).
Relative accumulated burned area	<i>%</i>	Sum of relative burned areas over time
Latest fire	<i>year</i>	Map for the year when the latest fire was observed, produced by reclassifying burned pixel values into year of observation, and then calculating the maximum per-pixel value among all overlapped annual raster maps.
Estimated time to burn the entire area	<i>years</i>	Time required to burn 100% of the area, calculated by a linear regression of the average native vegetation burned per year (%)

270 Previous research has suggested that annual burned area responds  
271 significantly to 1.5 to 2 years of accumulated rainfall before the end of the dry  
272 season in savannas ecosystems (Archibald et al., 2010; Balfour & Howison, 2002).  
273 Similarly, burned area in South American savannas is mainly determined by the  
274 cumulative amount of rain during the last 6 months of the dry season (Alvarado et  
275 al., 2020). We therefore used Generalized Linear Models (GLM), assuming a  
276 binomial distribution error with the logit link function (Table 3), to test how one and  
277 two years of rainfall accumulation (including one and two wet seasons, respectively)  
278 prior to the end of the dry season would affect total burned area. We also tested the  
279 effects of rainfall accumulation during the dry season (6 months prior to the end of  
280 the fire season). We considered each fire year as starting at the beginning of the  
281 wet season (October) and ending at the end of the following dry season (September  
282 of next year). We expected to find positive correlations between wet season rainfall  
283 and burned area (more rain increases fuel build-up during the rainy season and,  
284 consequently, increases burned area) and negative correlations between dry  
285 season rainfall and burned area (more rain during the dry season increases fuel  
286 moisture retention, reducing burned area).

287 We included the human component in our models as the interaction  
288 between two factors. Firstly, management practices were included as "conservation  
289 status", with three protection levels: "preservation", "sustainable use" and "buffer  
290 zone". Secondly, we considered the differences caused by human activities, such as  
291 land use management and agropastoral practices between locals, by explicitly  
292 including a variable named "site", represented by the three municipalities: Assis,  
293 Santa Bárbara, and Itirapina. We found that land use was similar among the study  
294 sites, with a few differences over time (Supplementary material Fig S2), as were  
295 tree cover patterns (Supplementary material Fig. S3).

296 We then interpreted the Akaike Information Criterion (AIC), the  $R^2$  and the  
297 ecological meaning of model coefficients to select the best-fitting model. We  
298 calculated  $R^2$  using the "MuMIn" package of the R package (R Core Team, 2020),  
299 which has a specific function to calculate  $R^2$  for generalized linear and mixed  
300 models (Nakagawa & Schielzeth, 2013). We applied the function  
301 "r.squaredGLMM()" to each resulting glm object, which outputs marginal (fixed

302 effects alone) and conditional (mixed effects)  $R^2$  values. However, since all  
 303 variables were included in the model as fixed variables, there was no difference  
 304 between marginal and conditional values, and we only retained the marginal  $R^2$ . All  
 305 spatial analyses were performed using the packages “raster” (Hijmans & van Etten,  
 306 2012) and “rgdal” (Bivand et al., 2015). Descriptive statistics and multiple linear  
 307 regressions were calculated in R 3.5.1 (R Core Team, 2018).

308

309 **Table 3.** Generalized linear model results. Relative burned area (BA, %) is summarized by  
 310 fire year (FY: October–September). Accumulated fire-year rainfall is the sum of the wet  
 311 season rainfall (October–March) and the dry season rainfall (April–September). Model in  
 312 bold was considered the best candidate model according to the selection criteria. The  
 313 symbol “:” represent the interaction between 2 factors.

<b>Regression model</b>	<b>R<sup>2</sup></b>	<b>AIC</b>
BA = 1 fire year rainfall	0.04	9.75
BA = 24 months before the end of dry season rainfall + 1 dry season rainfall	0.07	11.75
BA = 1 wet season rainfall + 1 dry season rainfall	0.09	11.75
BA = Site	0.31	11.77
BA = Conservation status	0.18	11.78
<b>BA = 1 wet season rainfall:site + 1 dry season rainfall:site</b>	<b>0.44</b>	<b>19.77</b>
BA = 1 wet season rainfall:conservation status+ 1 dry season rainfall:conservation status	0.29	19.77
BA = 1 wet season rainfall:site+ 1 dry season rainfall:site+ conservation status	0.51	23.79
BA = 1 wet season rainfall + 1 dry season rainfall + site:conservation status	0.46	27.79
BA = 1 wet season rainfall:site + 1 dry season rainfall:site + site:conservation status	0.53	31.80

314 **Table 4.** Parameter estimates for the best candidate model (BA =1 wet season rainfall:site  
 315 + 1 dry season rainfall:site)

<b>Parameter</b>	<b>Coefficient</b>
Intercept	-5
Wet season rainfall:Assis	0.00016
Wet season rainfall:Itirapina	0.00086
Wet season rainfall:Santa Bárbara	0.00086
Dry season rainfall:Assis	- 0.0069
Dry season rainfall:Itirapina	0.00079
Dry season rainfall:Santa Bárbara	- 0.0018

316

## 317 **Results**

318 *Relationships between rainfall, site, conservation status and burned area*

319

320 Contrary to our expectations, we did not find a strong correlation between  
321 rainfall and burned area. All models including rainfall variables only weakly  
322 explained annual burned area (coefficient of determination= 0.04, 0.09 and 0.07  
323 respectively, Table 3). However, as expected, we did observe positive coefficients  
324 for wet season rainfall, and negative coefficients for dry season rainfall, when  
325 predicting burned area (Table 4). When wet and dry season rainfalls were included  
326 as separate variables, they explained only 9% of variation in total burned areas.  
327 When human influence expressed by the factor “site” was added to rainfall in both  
328 seasons, these variables together explained 44% of variation in the total burned  
329 area. This interaction was stronger than that obtained with the human component  
330 defined by “conservation status”, which explained only 29% of burned area with  
331 same AIC value of 19.77. The inclusion of interactions between the two human  
332 components (“site” x “conservation status”) or between both components and wet  
333 and dry season rainfall resulted in higher AIC values and only marginal gains of  
334 explanatory power in relation to our best model.

335 Examining the coefficients of the selected best model, relative burned areas  
336 are positively affected by wet season rainfall in all sites. Coefficients were similar for  
337 Itirapina and Santa Bárbara; in Assis, however, the value was ca. 1/5 of those  
338 obtained for the other sites. Conversely, dry season rainfall negatively affected  
339 burned area, with a coefficient value for Assis four times higher than that for Santa  
340 Bárbara. Interestingly, a slightly positive coefficient was observed for Itirapina,  
341 indicating that dry season rainfall is either neutral or slightly increases burned area  
342 in this site.

343

#### 344 *Spatial and temporal dynamics of fire*

345

346 We detected 49 471 hectares of burned areas (BA), distributed among 1 607  
347 ignitions between 1985 and 2017 for all three study sites. From this total, 93% of the  
348 ignitions and 91% of the total burned area were observed for Itirapina, followed by  
349 Santa Bárbara (6% of ignitions and 8% of total burned area) and Assis (2% of  
350 ignitions and 1% of total burned area). Small burn scars (less than 0.5% of relative  
351 area) were the most frequent burn events in all sites, while large burned areas were  
352 rarely observed (Figure 2A).

353 The Assis protected area (AES) was burned only once by a small burn (<  
 354 0.5% of total area), remaining otherwise without fire over the entire period analyzed  
 355 (Figure 2B). We observed the same pattern of peaks in burned area for Santa  
 356 Barbara (SBES) and Itirapina (IES) protected areas, characterized by 7- to 9-year  
 357 periods without fire followed by a peak in burned area (Figure 2B). Considering the  
 358 total extent of fire scars in the protected areas over 33 years, the amount of native  
 359 vegetation burned per year is only 0.02% in Assis, 2.03% in Santa Bárbara and  
 360 3.37% in Itirapina. If we disregard overlapping fire scars, the situation is even worse  
 361 (Table 5), with most areas in the three study sites not being burned over the last 33  
 362 years (99.3% in Assis, 57.2% in Santa Bárbara and 44.7% in Itirapina).

363

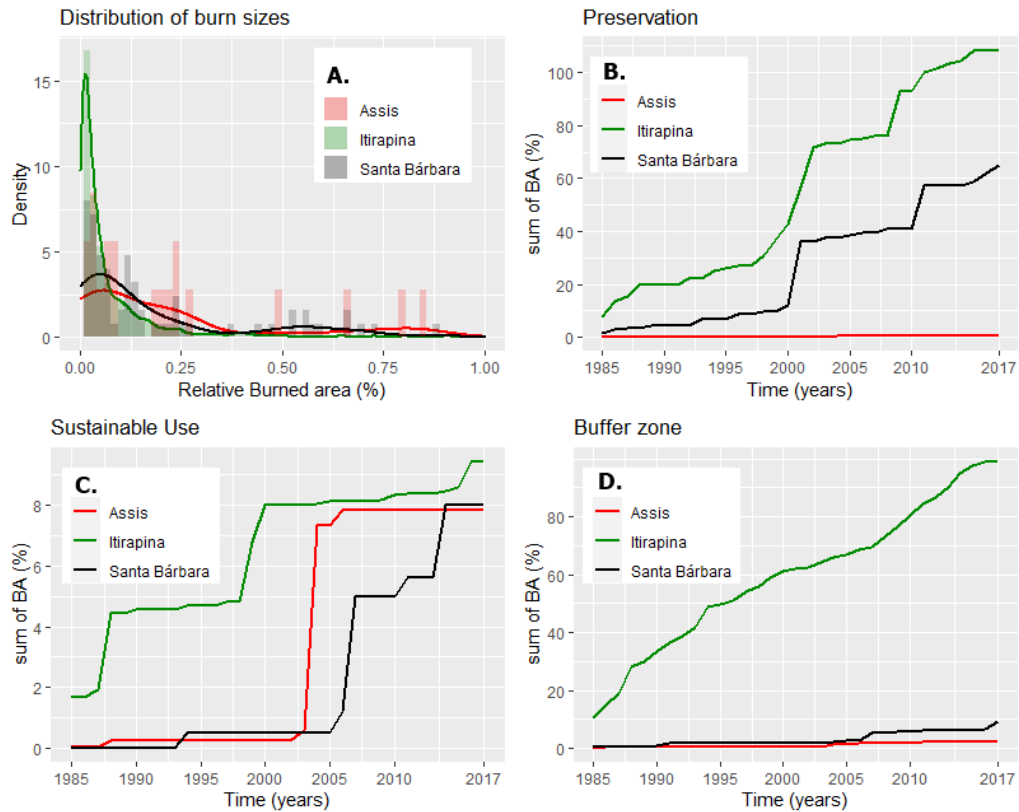

364 **Table 5.** Historical distribution of native vegetation areas burned at least once in 33 years  
 365 (1985–2017) within the studied protected areas. \*Time estimated to burn the entire  
 366 preservation area was estimated using the historic burn rate (% native burned per year).

	<b>Assis</b>	<b>Santa Bárbara</b>	<b>Itirapina</b>
<b>Native vegetation (ha)</b>	1755	2796	2677
<b>Native vegetation burned at least once in 32 years (ha)</b>	12	1195	1480
<b>Native vegetation never burned</b>	1743	1601	1197
<b>% mean native burned per year</b>	0.02	1.33	1.72
<b>% native vegetation never burned</b>	99.3	57.2	44.7
<b>*Time estimated to burn the entire reserve (years)</b>	5000	~ 75	~ 58

367

368 In general, the areas under sustainable use in all sites (ASF, SBSF and  
 369 IExS) had a low increase in accumulated burned area over time, punctuated by  
 370 abrupt increases when single wild fires burned large areas of pine plantations  
 371 (Figure 2C).

372 We observed the lowest fire occurrence in Assis and Santa Bárbara buffer  
 373 zones, where only a few areas burned during the study period (Figure 2D). In the  
 374 Itirapina buffer zone, however, we observed high and continuous fire usage (Figure  
 375 2D).

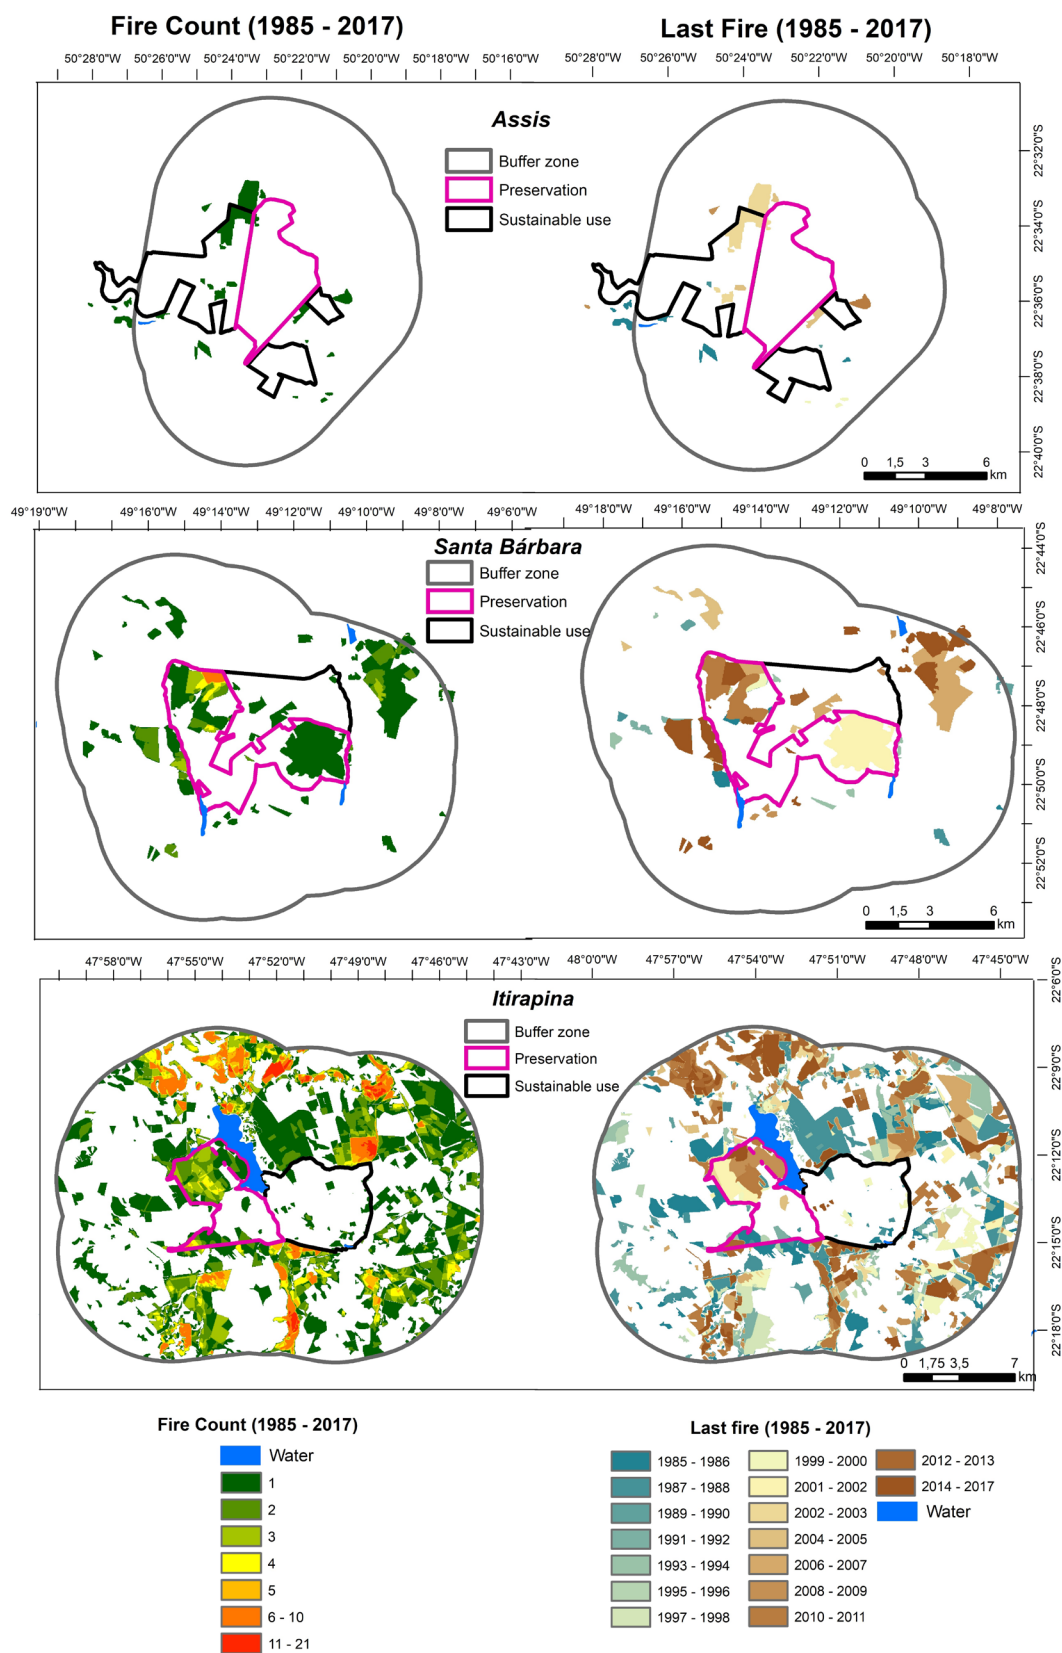

376

377 **Figure 2.A.** Burn-scar size distribution (density) per site, considering relative burned area of  
 378 each burn (%). Relative accumulated burned area (%) between 1985 and 2017 for: **B.**  
 379 protected areas; **C.** sustainable use areas; **D.** buffer zones.

380

381 At the three study sites, burn scars had predominantly regular geometries  
 382 (Figures 3A/B/C). The Assis preservation area had the lowest fire frequency, and  
 383 the only observed burn scar was related to a shared burned scar within the  
 384 contiguous sustainable use area and buffer zone (Figure 3A). Itirapina and  
 385 particularly Santa Barbara protected areas had a higher fire frequency within their  
 386 limits when compared to their buffer zones (Figure 3B/C), but fire scars spanning  
 387 both protected area and buffer zones were also detected. The buffer zone of  
 388 Itirapina had the highest fire count among all studied areas (Figure 3C). Concerning  
 389 time since last fire, we observed that sites with a higher fire frequency tended to be  
 390 burned more recently. In Santa Bárbara, the majority of burned areas were recent,  
 391 while Itirapina had a pattern of large areas burned only once, followed by no  
 392 recurrence of fire during the last 20 years.

393

394

395 **Figure 3.** Fire count and year of the last fire from 1985 to 2017 for the regions of: **A.** Assis;  
 396 **B.** Santa Bárbara; **C.** Itirapina.

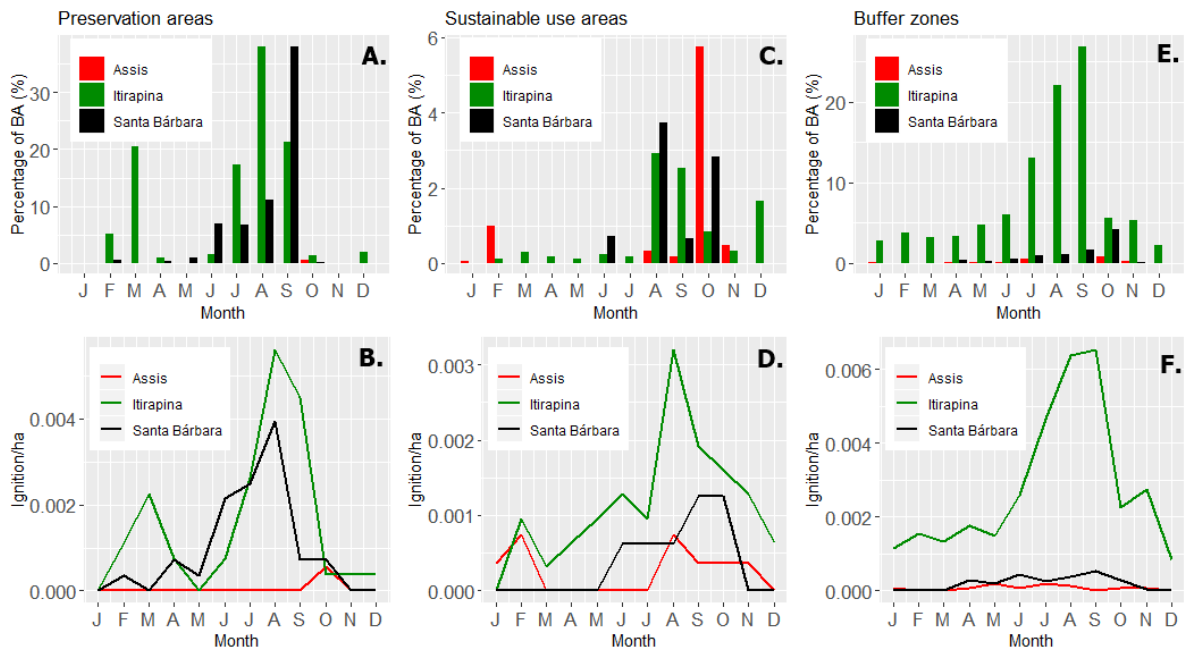

397

398

399 *Fire seasonality*

400 In general, the peak of ignitions and burned area in all sites, independent of  
401 conservation status, was concentrated in mid and late dry season (July–  
402 September). A second, abnormal peak of ignitions and size of burned area was  
403 observed for the Itirapina protected area (Figure 4A/4B) and the Assis sustainable  
404 use area (Figure 4C/4D), both during the transition between the rainy and dry  
405 seasons in February–March. The Itirapina buffer zone had a higher fire frequency  
406 than the other buffer zones, burning in all months of the year, with increased fire  
407 activity during the dry season.

408

409 **Figure 4.** Monthly sum of relative burned area (%) from 1985 to 2017 and density of  
410 ignitions (ignition/ha) for: **A/B.** Preservation areas; **C/D.** Sustainable use areas; **E/F.** Buffer  
411 zones.

412

413

414

415 **Discussion**

416 *Fire Seasonality*

417 The peak of fire occurrence, in terms of number of ignitions and amount of  
418 burned areas, occurred by the end of the dry season and the beginning of the rainy  
419 season (October). This pattern has also been observed for other areas in the  
420 Cerrado, likely resulting from the balance between fuel load build-up during the

421 rainy season and a decrease in fuel moisture during the dry season, which together  
422 determine the probability of ignition (Alvarado et al., 2017; Ramos-Neto & Pivello,  
423 2000). The peak of ignitions and burned area during the late dry season (August–  
424 September) in human-impacted savannas is often related to the use of fire to  
425 support cattle grazing and cropping (Mataveli et al., 2018; Pivello, 2011). Within  
426 protected areas, the main cause of late dry season fires are lightning ignitions  
427 (when natural fire occurs) and accidental or arson fires (Batista et al., 2018). This  
428 pattern of human-driven fires in savannas during the late dry season has also been  
429 reported in several protected and non-protected areas in Brazil and Africa (Alvarado  
430 et al., 2017, 2018; Archibald, 2016; Fiedler et al., 2006; Medeiros & Fiedler, 2004;  
431 Pereira Júnior et al., 2014). Late fires are more intense than early fires and are  
432 often associated with a decrease in the density and diversity of the woody  
433 vegetation layer (Govender et al., 2006), potentially causing mid-term changes in  
434 plant communities.

435         Secondary ignition peaks were observed at the end of the rainy season  
436 (February–March). These lower peaks were described by Ramos-Neto & Pivello  
437 (2000) as natural fires caused by lightning. We observed fire scars at the end of the  
438 rainy season, characterized by regular geometries neighboring buffer zones and  
439 roads, indicating they were likely human set-fires and not caused by lightning.

440

#### 441 *Climate influences on fire regime*

442         We found a positive effect of rainfall during the rainy season and a negative  
443 effect of rainfall during the dry season on annual burned area in most of our study  
444 sites except in Itirapina, where a slightly positive effect of dry-season rainfall on  
445 annual burned area was observed. In our study, the accumulated rainfall explained,  
446 in small part (9%), the extent of burned areas. This predictability is low compared to  
447 the 38% explanation obtained in Cerrado areas of Minas Gerais (Alvarado et al.,  
448 2017). We have not found a relevant relationship between accumulated rainfall and  
449 the amount of burned areas, as rainfall effects showed low  $R^2$ , suggesting that the  
450 human component can buffer the climate-fire relationship (Bird et al., 2012).

451         The amount of rainfall during the wet season determines productivity and  
452 fuel accumulation, while the amount of rainfall during the dry season determines the  
453 probability of ignition (Bradstock, 2010; Cochrane & Ryan, 2009). Moreover, among

454 mesic savannas under similar climate conditions, differences in vegetation structure  
455 (e.g. percentage of grasses, shrubs and tree cover) alter fuel build-up, composition,  
456 moisture conditions and fuel availability in the dry season. These differences modify  
457 the fire-climate interaction and creating alternative stable states of vegetation  
458 maintained by fire-vegetation feedbacks (D'Onofrio, et al., 2018; Lasslop et al.,  
459 2018; Lehmann et al., 2014).

460 The positive effect of dry-season rainfall on burned areas observed in  
461 Itirapina contradicts what has been reported in the literature for wet savannas  
462 (Alvarado et al., 2020). A higher frequency of lightning with higher dry season  
463 rainfall could explain that result, but no empirical data about lightning fires was  
464 available. Given this almost neutral effect, we assume that the positive effect  
465 resulting from the model may be a spurious correlation. Also, human impact may be  
466 'buffering' the climate-fire regime, as shown for Australian savannas (Bird et al.,  
467 2012).

468

#### 469 *Human influence*

470 Burn scar geometries were regular in all sites, independent of conservation  
471 status, indicating a highly managed landscape (Cochrane & Ryan, 2009). São  
472 Paulo's state law (10 547/ 2001) requires the establishment and yearly maintenance  
473 of firebreaks of at least 3 meters width around infrastructure (e.g. roads, railways,  
474 power transmission lines) and 6 meters width around croplands, pastures and  
475 protected areas. These firebreak arrangements explain the appearance of regular  
476 burn scar geometries, as human activities can modify fire-climate relationships by  
477 increasing landscape fragmentation through roads, railways and infrastructure  
478 (Andela & van der Werf, 2014).

479 Since natural fires are rare in São Paulo state due to the massive presence  
480 of lightning rods, most observed fires were likely caused by humans. Roads can be  
481 an agent of such human-caused fires. While fragmenting the landscape, roads also  
482 enable people to travel through the savannas. Thus roads act both as firebreaks  
483 and potential ignition points at the same time. Accidental and arson fires ignited  
484 near preservation areas can spread into them and reshape fire regimes (Archibald,  
485 2016; Daldegan et al., 2014). These modified fire regimes are considered among  
486 the threats to Cerrado conservation (Durigan et al., 2007).

487           Despite the study sites sharing similar management regimes, we found  
488 remarkable differences in fire regimes among sites, in terms of both the number of  
489 ignitions and annual burned area. In the buffer zones, fire regimes were highly  
490 human-managed, in terms of decreasing or increasing fire frequency. The  
491 differences between buffer zone fire regimes are related to differences in local  
492 agropastoral practices. Whereas fire is often used to renew large pastures in  
493 Itirapina and Santa Bárbara, the ranchers in Assis practice "pasture rotation". This  
494 practice involves dividing pastures into small plots and moving cattle among them  
495 over the year, thus preventing pasture exhaustion and stimulating regrowth without  
496 fire.

497           Moreover, the conversion of pastures into cropland, which automatically  
498 reduces fire frequency, has been observed in all study sites since 2005  
499 (Supplementary material Fig S2). In Assis and Santa Bárbara, pastures transition to  
500 other crops (e.g. soybean, corn) or to sugarcane on flat terrain, where mechanized  
501 harvest and fire exclusion are practiced. In Itirapina, however, where pastures  
502 transition to sugarcane in high-slope areas, fire has been used until recently to  
503 facilitate sugarcane harvesting.

504           Concerning the effect of "conservation status" on fire regimes among our  
505 study sites, our results suggest that it corresponds, although in a discreet way, to  
506 the type of fire management that has been applied. While prescribed fire  
507 management has been implemented in agricultural areas in the buffer zones for  
508 decades, a successful fire exclusion policy has been simultaneously implemented  
509 inside the sustainable use forestry areas. This policy has not been as "successful"  
510 in the protected areas occupied by cerrado vegetation. When we considered  
511 "conservation status" effects alone in a model (coefficient of determination= 0.18),  
512 we observed a consistent increase of annual burned area in the cerrado  
513 preservation areas ( $B = 0.47 \% \text{ yr}^{-1}$ ) and a decrease of annual burned area in  
514 sustainable use areas ( $B = -1.54 \% \text{ yr}^{-1}$ ) when compared with the buffer zones.

515           Despite preservation and sustainable use areas being completely different  
516 in ecological terms, these areas are managed by a single institution and share  
517 similar fire exclusion policies and enforcement. We found a very low proportion of  
518 fire activity on native vegetation in the studied preservation areas, far below the 5-  
519 year fire return interval reported for Cerrado historical fire regime (Dias, 2006). The  
520 adopted fire-exclusion policies significantly reduced fire frequency and number of

521 ignitions, increasing fire return intervals in all preservation areas studied. However,  
522 the reduced number of ignitions and increased fire return intervals may be  
523 associated to a high fuel load accumulation, leading to larger burned areas  
524 (Alvarado et al., 2018; Keeley et al., 1999; Miranda et al., 2009).

525         Large wildfires were observed in IES and SBES every 7–9 years of fire  
526 absence, highlighting that anthropic pressures can lock Cerrado into a fire paradox,  
527 where fire exclusion prevents fires in the short term but causes repeated wildfires in  
528 the midterm (Arévalo & Naranjo-Cigala, 2018). Fire occurrence was lower in AES,  
529 partly explained by lower fire pressures from the buffer zone. However, despite all  
530 buffer zones having similar land use patterns (Supplementary material Fig S2) and  
531 tree cover over time (Supplementary material Fig S3), as that of the sustainable use  
532 areas, we observed a large difference among the study sites in the dominant  
533 vegetation within the protected area. While AES was dominated by cerradão, a  
534 forest-like vegetation, IES and SBES were mostly occupied by grassland/savanna  
535 vegetation during the study period (Supplementary material Fig S2 and S3). The  
536 closed and evergreen canopy of the high tree biomass cerradão vegetation  
537 increases fuel moisture and decreases flammability (Barbosa & Fearnside, 2005;  
538 Miranda et al., 2009; Newberry et al., 2020). Thus, even if buffer zone fire pressures  
539 were stronger, native vegetation in AES would rarely burn as much as that in IES or  
540 SBES.

541         We found a similar fire regime in all sustainable use areas, which can be  
542 explained by the similarities in size, geometry and species composition (e. g. *Pinus*  
543 spp., *Eucalyptus* spp.) of the forestry stands. The tree composition and closed  
544 canopy of these forestry stands create low luminosity conditions and prevent the  
545 establishment of native Cerrado grasses and shrubs in the understory (Viani et al.,  
546 2010). However, the slow decomposition rates of pine needles and *Eucalyptus*  
547 leaves in the litter increases fuel load and thus the long-term flammability of the  
548 system, unlike the Cerrado's fast fuel build-up (Beutling et al., 2012; Ribeiro, 2013).  
549 Long-term fire absences and fuel load accumulation increases the probability of  
550 wildfires in arid pine ecosystems (Glitzenstein et al., 2003). In regions with humid  
551 climates, however, a trade-off between fuel loads and high moisture retention in the  
552 litter could limit ignitions and fire spread.

553         In terms of management, fire needs to be seen not as an enemy of Cerrado  
554 conservation, but as an ally. Once preservation areas become extremely

555 fragmented and are under pressure from a complex anthropic matrix, prescribed  
556 fires, rather than fire exclusion, become crucial for the conservation of a fire-prone  
557 ecosystem like Cerrado, whose biodiversity is severely threatened by fire  
558 suppression (Abreu et al., 2017). In ecological terms, it is difficult to establish a  
559 suitable management without testing and assessing the effects of different fire  
560 regimes. Thus, management plans cannot be a “one-size-fits-all” recipe for  
561 prescribed fires—they need to include the prerogative of managers to test and apply  
562 management according to observed effects.

### 563 *Conclusion*

564 Fire regimes are highly variable in terms of frequency and extent of burned  
565 area among sites under similar climates, showing that other factors, largely human-  
566 related, have a stronger local effect than climate. The probabilities of accidental and  
567 arson fires are related to human-set fires in mid-late dry season. Our study detected  
568 a high proportion of the native vegetation not being subjected to any burning over  
569 the last 33 years, a direct result of the extensive fire exclusion policy adopted in  
570 Brazil 50 years ago. This has modified the fire regime of protected areas and  
571 decreased fire frequency in comparison to historical fire regimes of the Cerrado.

572 The exclusion of fire in protected areas of São Paulo state has severely  
573 affected their fire regimes by 1) precluding fires for much longer periods than  
574 historically observed for the biome, and 2) concentrating arson and accidental fires  
575 towards the end of the dry season, especially in sites where open savanna  
576 vegetation exists and fuel build-up is high. To mitigate the negative effects of these  
577 modified fire regimes on Cerrado ecosystems and their biodiversity, conservation  
578 policies need to change. Although fire prevention may be appropriate for  
579 sustainable use forestry areas, fire exclusion is not a suitable policy for protected  
580 areas of fire-prone ecosystems such as the Cerrado. New management strategies  
581 must therefore include legislation that supports protected area managers in  
582 planning and applying prescribed fires in Cerrado preservation areas.
