ABSTRACT

Bookmakers sell claims to bettors that depend on the outcomes of professional sports events. Like other financial assets, the wisdom of crowds could help sellers to price these claims more efficiently. We use the Wikipedia profile page views of professional tennis players involved in over 10,000 singles matches to construct a buzz factor. This measures the difference between players in their pre-match page views relative to the usual number of views they received over the previous year. The buzz factor significantly predicts mispricing by bookmakers. Using this fact to forecast match outcomes, we demonstrate that a strategy of betting on players who received more pre-match buzz than their opponents can generate substantial profits. These results imply that sportsbooks could price outcomes more efficiently by listening to the buzz.

1. Introduction

The size and ubiquity of online sports betting markets continues to increase. Most notably in recent years, the world's most successful online sportsbooks entered the U.S. after a 2018 Supreme Court ruling allowed states to legalise gambling at their own discretion. As online

sports betting markets have grown and replaced more traditional forms of gambling, lower transaction costs have increased competition and driven down bookmaker profit margins (i.e., the 'overround' or 'vig') (Forrest, 2008). Over the same period, the amount of online information that bettors can use to form expectations about sports outcomes has increased. This includes detailed historical data about the participants and the setting of an event, the commentary and predictions of sports pundits and tipsters, and the so-called 'wisdom of crowds'. This latter term is used widely to describe instances where information aggregated from the decisions of many individuals improves forecasting and decision-making processes, compared with relying on a small number of expert positions (Galton, 1907; Surowiecki, 2004). Given the small profit margins and competition with the crowd-based betting exchanges (prediction markets), odds-setters may need to forecast outcomes and price the claims they sell to bettors more efficiently than ever before. It is natural to ask whether bookmakers are doing this successfully. In this paper, we use a specific practical example to demonstrate how online sportsbooks are vulnerable to information that could represent the wisdom of crowds.

Wikipedia, the free online encyclopaedia, is an example of crowd wisdom. It has become the go-to online place for information about almost anything, including the characteristics and form of sports people. We use this fact to construct what we call the Wiki Relative Buzz Factor, for over 10,000 Women’s Tennis Association (WTA) singles matches since the beginning of the 2015 season. These matches were all at the elite level of the sport and include the four annual Grand Slam tournaments. The buzz factor uses the number of page views on the Wikipedia profiles of players before their matches began. We call it ‘relative’ because it compares the players within a match. We call it ‘buzz’ because it uses the profile page views on the day before a match in proportion to the typical numbers over the past 12 months. We then adapt the Mincer and Zarnowitz (1969) forecast evaluation framework, showing that the Wiki Relative Buzz Factor can significantly predict the systematic mispricing of bookmaker odds, with the higher-buzz player being underpriced. There is no significant evidence of a favourite or longshot bias in these markets, but bookmakers tended to significantly underprice a player who was substantially lower-ranked than her opponent. Taking these results together, we can reject a sufficient condition for weak-form market efficiency. To prove that these markets are inefficient, we generate probability forecasts of tennis match results by using the same model that detected the mispricing. Combining these forecasts with the Kelly criterion, which can be motivated from expected utility theory, we demonstrate substantial and sustained profits from exploiting the information contained in the Wiki Relative Buzz Factor. Specifically, we found a potential return on investment of 17%-29% from applying the forecasting model at Bet365, the world’s highest revenue online sportsbook, to over 5000 potential bets on WTA matches between the beginning of the 2019 season and March of 2020. In contrast, using probability forecasts from the widely used (Elo, 1978) rating systems and the Kelly criterion would have generated substantial losses over the same samples of matches.

These results contribute to the growing literature attempting to elicit the value of crowd wisdom from the field and using this to test the efficient market hypothesis (Fama, 1965, 1970). Relevant to our study of betting markets, research has demonstrated how information from social media can predict what happens in financial markets, including cross-sectional stock returns (e.g., Avery et al., 2016; Chen et al., 2014; Sprenger et al., 2014) and the price movements of cryptocurrencies (Kraijjeveld & De Smedt, 2020). Specifically using Wikipedia, Moat et al. (2013) found that activity on relevant financial pages could provide some early signs of stock market movements. Behrendt et al. (2020) also found that activity on Wikipedia pages could be used to infer collective investor behaviour and design a trading strategy for individual stocks. In a study closely related to our own, Brown et al. (2018) discovered that the aggregate tone extracted from a large number of Twitter posts contained significant information not present in live betting-exchange prices during football matches, especially in the aftermath of major events such as goals or red cards. Using a crowd explicitly making predictions, Brown and Reade (2019) found that the aggregated content from a community of online sports tipsters also contained information not present in betting prices. Betting when the majority of the community predicted a particular outcome generated a small average positive return. Peeters (2018) also found that a crowd of sports fans could improve forecasting accuracy and generate profitable opportunities on betting markets. Specifically, forecasts based on the football player transfer market values on transfermarkt.de and the implied strengths of international teams proved more accurate than other standard predictors of match results, such as official team rankings or form-based rating systems.

This paper contributes more generally to the literature on the efficiency of betting and prediction markets, specifically for sports, much of which has focused on the favourite–longshot bias (for reviews, see Williams, 1999, Ottaviani & Sørensen, 2008, or Newall & Cortis, 2021). There is some literature focused on the efficiency of tennis-match betting markets (Abinzano et al., 2016, 2019; Forrest & Mchale, 2007; J., 2014; Lyócsa & Výrost, 2018). This literature has tended to find evidence of a longshot bias that is not large enough to overcome the bookmaker profit margin and prove inefficiency. The present paper also contributes to the use of professional sports to learn about the practice of forecasting, in particular to some studies that have focused on professional tennis (e.g., Angelini et al., 2021a; Barnett & Clarke, 2005; Candila & Scognamillo, 2018; del Corral & Prieto-Rodriguez, 2010; Easton & Uylangco, 2010; Knottenbelt et al., 2012; Kovalchik, 2020; Kovalchik & Reid, 2019; McHale & Morton, 2011; Scheibehenne & Broder, 2007; Spanias & Knottenbelt, 2013). The forecasting models introduced by these studies cannot normally outperform bookmakers without shopping around to find the best available odds (Angelini et al., 2021a; Kovalchik, 2016).

The rest of the paper proceeds as follows: Section 2 describes our dataset, a model to detect mispricing, and a simple betting strategy to test market efficiency using the model; Section 3 presents the results; and Section 4 concludes.

2 Data & method

We collected information from tennis-data.co.uk for all WTA match results from the main draws of all tournaments, including the Grand Slams, between January 1, 2015 and February 16, 2020. This information includes the identity of players and tournaments, as well as when

---

2 Wikipedia is the seventh most visited website worldwide; see https://www.similarweb.com/top-websites/, retrieved May 11, 2022.

3 We have no particular rationale for focusing on this sport and the women’s game only. However, it is convenient that odds on all these events were offered by a large number of online sportsbooks. Further, we had built a dataset containing information about these events for other research projects before using it to explore the questions in this paper.

4 These tennis match data are readily available before 2015, but our analysis period is restricted by the availability of historical Wikipedia page-view data.
The local date gives the match start, which is important since matches can be played over multiple days due to stoppages, for example, due to the weather.

See http://www.tennisabstract.com/blog/category/match-length/.

Fig. 1. Wikipedia daily page views of tennis players before WTA matches from 2015–2020. Notes. Author calculations using Wikipedia Foundation page-view data for the English-language profiles of WTATennis players, collected daily (Coordinated Universal Time (UTC)) using the Pageview Application Programming Interface (API). The densities are estimated with a Gaussian kernel and bandwidth of 0.2.

(a) The day before the match

(b) Median in the year before the match

(c) Relative Buzz Factor: log difference between the winner’s page views on the day before the match and the winner’s median daily views in the year before, relative to the loser

number of matches in a sample, such that the overall sample contains 2J player–match observations. Let $p_j$ be the unobserved beliefs of the bookmaker about the probability of $y_{ij} = 1$ happening beforehand, i.e., player 1 winning match $j$. The bookmaker offers decimal odds $o_{ij}$ on the two potential outcomes, meaning that, on taking a £1 bet, they return $o_{ij}$ to the bettor if the outcome happens, and they gain £1 if it does not. Let $z_{ij} = 1/o_{ij}$ be the inverse odds or implied odds-based probability forecast of the bookmaker. For any match, $z_{ij} + z_{2j} = 1 + \kappa_j > 1$, where $\kappa_j$ has often in the literature been termed as the bookmaker’s expected rate of commission or profit margin on a match, also known among sports bettors as the ‘overround’ or ‘vig’. This implies $z_{ij} = p_j + \alpha \kappa_j$ and $z_{2j} = (1 - p_j) + (1 - \alpha) \kappa_j$. If we denote $e_{ij} = y_{ij} - z_{ij}$, then an efficient bookmaker market requires that forecast errors on average are equal to the negative value of some sample average ‘overround’, $E_{ij}[e_{ij}] = -\bar{\kappa}$. In other words, the bookmaker is efficient if it makes some average level of commission across matches and outcomes, and no other information can predict $e_{ij}$, since it would already be priced into the odds.

We consider three potential sources of mispricing and departures from the efficient market hypothesis in WTA betting markets.

(1) Favourite–longshot bias: There is an empirical irregularity in some prediction and betting markets known as the favourite–longshot bias. When it has been used in the academic literature, this term most typically equates to a longshot bias, whereby the odds offered by bookmakers suggest an underestimation by the market about the chances of the most expected outcomes happening over the least expected outcomes, making bets on favourites generally more profitable than bets on longshots (see the summaries by Ottaviani & Sørensen, 2008 and Newall & Cortis, 2021). Many studies of professional sports betting markets have identified such a longshot bias, including the seminal study on horseracing by Ali (1977).
Several theoretical contributions, which could be broadly classified as coming from neoclassical economic theory, have demonstrated the sufficient conditions such that this longshot bias can arise in equilibrium, in terms of the preferences, budget constraints, and distribution of beliefs among the market participants (e.g., He & Treich, 2017; Manski, 2006; Ottaviani & Sørensen, 2015). The same theoretical frameworks also suggest that high risk aversion among bettors can lead to the bias reversing toward the favourite outcome in the market, which is often termed reverse favourite–longshot bias or just favourite bias. Besides the predictions from neoclassical economic theory, a competing set of behavioural explanations has been proposed to explain the favourite–longshot bias, which emphasises the misperception of probabilities by bettors (e.g., Snowberg & Wolfers, 2010; Vaughan Williams et al., 2018). Newall and Cortis (2021) suggest from their review of the empirical literature that sports markets with fewer potential outcomes tend to produce a favourite bias (e.g., team sports or tennis), whereas a longshot bias appears in markets with many outcomes (e.g., horseracing or golf). Nevertheless, previous studies of professional tennis have found a longshot bias (e.g., Abinzano et al., 2016, 2019; Forrest & Mchale, 2007; J., 2014), though not sufficient to suggest market inefficiency through positive mean returns from consistently betting on match favourites (e.g., Forrest & Mchale, 2007; Lyócsa & Výrost, 2018).

(2) Player ranking bias: We consider whether tennis betting markets systematically misprice the outcome of a match according to player rankings. Several studies have demonstrated how the recent performances of tennis players can provide relatively accurate forecasts compared with those implied by bookmaker odds as a benchmark, typically through enhanced (Elo, 1978) ratings (e.g., Angelini et al., 2021a; Kovalchik, 2020; Kovalchik & Reid, 2019). We use standard and more advanced Elo ratings below to provide benchmark probability forecasts of match results.8 There is some suggestive evidence that bookmakers are more risk averse in tennis matches involving lower-ranked players, and the longshot bias thus increases in these cases (Abinzano et al., 2016; J., 2014). The WTA world rankings are ordered from one, for the best player cumulatively over the past year, to having no rank, for a player who has not earned enough points at WTA events over the past year to get one. We consider two measures based on these rankings. First, we consider the raw rank difference between the players in a match, RankDiff\(_{ij}\) = rank\(_i\) − rank\(_j\). Second, we assume that the performance difference between two consecutive players in the rankings is decreasing more so as one goes down the ranking list from the top. The difference in ability between the first- and second-ranked players is likely to be more than between the 100th- and 101st-ranked players, which can be evidenced by how much less often player rankings move at the top compared with the bottom. We construct a ranking distance measure for player \(i\) in match \(j\) as:

\[
\text{RankDist}_{ij} = -\left(\frac{1}{\text{rank}_{ij}} - \frac{1}{\text{rank}_{j}}\right),
\]

where we impute 1/rank\(_j\) = 0 if a player was unranked at the time of a match. RankDist\(_{ij}\) is bounded by −1, when the player considered is ranked first in the world and is playing somebody unranked, and 1, when it is the other way around, thus having the same sign interpretation as RankDiff\(_{ij}\).

(3) Wikipedia Relative Buzz Factor bias: To the best of our knowledge, this sort of information has not been used to predict the outcome of tennis matches and the efficiency of their betting markets, or at least this has not been documented before. However, there are parallels with studies using information from social media and player evaluations to predict football match outcomes and betting inefficiencies (e.g., Brown et al., 2018; Peeters, 2018).

To detect mispricing and estimate the conditional mean effects on bookmakers’ odds-implied probability forecast errors, we apply the general (Mincer & Zarnowitz, 1969) forecast evaluation framework (see Angelini & L., 2019, Angelini et al., 2021b, and Elaad et al., 2020, who tested for home bias, the favourite–longshot bias, and the weak-form efficiency of European football betting markets in much the same way). We estimate the following using least squares:

\[
e_{ij} = \alpha + \beta_1 z_{ij} + \beta_2 \text{RankDist}_{ij} + \beta_3 \psi S(j) + \beta_4 \psi T(j) + \epsilon_{ij},
\]

where \(\{\alpha, \beta_1, \beta_2, \beta_3, \psi S(j), \psi T(j)\}\) are parameters. We expect a significantly negative estimate of \(\alpha\) to capture the bookmaker’s profit margin (overround). Positive values of \(\beta_1, \beta_2,\) or \(\beta_3\) would respectively suggest a longshot bias, a high-rank bias, or a low-buzz bias in the markets, such that betting on a win by the favourite, the lower-ranked player, or the one with greater pre-match relative buzz could be profitable strategies, and vice versa if these parameters are negative. We also consider fixed effects in Eq. (3) for the season (year), \(\psi S(j)\), and tournament of the match, \(\psi T(j)\), where \(S(j)\) and \(T(j)\) are indicator functions, to address the potential heterogeneity over these dimensions in bookmaker overrounds or expected profit margins. The remaining heterogeneity is left in the residual term \(\epsilon_{ij}\). We construct standard errors for the estimates of Eq. (3) that are robust to clusters at the match and tournament levels. This addresses the heteroskedasticity from including both players in a match in the estimation sample, as well as the possibility that some tournaments may be less predictable than others.9

The mean of \(\epsilon_{ij}\) will be significantly negative for any reasonably sized sample of matches. Therefore, a sufficient condition for the betting market to be weak-form

---

8 The Elo ratings are computed using all WTA tennis matches between the beginning of the 2007 season and March 2020.

9 As a robustness check, we also considered estimates of Eq. (3) using weighted least squares, with elements of the diagonal weighting matrix approximated by \(v_1 N \times v_2 N\), as suggested by Angelini and L. (2019). Although this estimator reduces the influence of more competitive matches, the results that follow are robust to using this instead of ordinary least squares.
efficient, according to Eq. (3), is given by the null hypothesis: $H_0 : \beta_1 = \beta_2 = \beta_3 = 0$. If we find that estimates of $[\beta_1, \beta_2, \beta_3]$ are significantly positive or negative, then the associated variables provide information that is not fully incorporated in the pre-event prices. In this case, the markets may be inefficient if bettors can use the same information to make sustained positive returns.

2.3. Market inefficiency and a simple betting strategy

To test whether the bookmaker markets are inefficient, we use estimation results of the mispricing model in Eq. (3), an out-of-sample dataset of tennis matches, bookmaker odds and Wikipedia page-view data, and the Kelly (1956) criterion. This criterion is the solution to a bettor’s maximisation problem on how much of the bettor’s wealth should be invested in the claim offered: the oddsposted by the bookmaker. Along with simpler strategies such as ‘bet one unit when the expected return is positive’, the Kelly criterion has been widely used in the literature to evaluate betting market efficiency (e.g., Hvatum & Arntzen, 2010; Peeters, 2018; Ziemba, 2020). We assume that our bettor in this case forms expectations based (Elo, 1978) ratings, with an updating factor (K-factor) of 20, and using all WTA match results since the beginning of the 2007 season. We also use the more sophisticated W-Elo forecasting model from Angelini et al. (2021a).

3. Results

3.1. Mispricing

Table 1 shows the results of estimating Eq. (3) for an in-sample period of the 2015–2018 WTA seasons, using as the dependent variable the value of the prediction error according to the mean pre-match odds offered by the $K_k$ (normally 40–60) individual bookmakers ($k = 1, \ldots, K_k$) listed by oddsportal.com for any given match: $\hat{e}_{ij} = y_{ij} - \sum_{j}^{K_k} (z_{ijk}/K_k)$. Column (I) only tests for a favourite–longshot bias. We find on average a marginal favourite bias, but this is not statistically significant. Column (II) adds the difference in the pre-match WTA rankings of the players, RankDiff, as a regressor, which is also not statistically significant. When taken together with the favourite–longshot bias, the null $H_0 : \beta_1 = \beta_2 = 0$ cannot be rejected, and there is no evidence that bookmaker betting markets for WTA tennis matches are mispriced according to the raw difference in ranks and the balance of the odds between players.

In column (III) of Table 1, we replace RankDiff$_{ij}$ with our alternative measure of the rank difference between players, RankDist$_{ij}$. This measure significantly predicts the average bookmaker odd-implied forecast errors ($p$-value = 0.035), and the null $H_0 : \beta_1 = \beta_2 = 0$ cannot be rejected at the 10% level. The model estimates suggest that the probability of an unranked player winning against the number one ranked player in the world is 0.061 greater than what bookmaker odds tend to imply. In column (IV), we add the third potential source of mispricing to the model in the form of the Wiki Relative Buzz Factor. This measure positively and significantly predicts the average bookmaker odd-implied forecast errors ($p$-value = 0.030). As mentioned before, on average the player with a relatively larger pre-match increase in Wikipedia profile page views tends to lose a tennis match. However, the model estimates show that bookmaker odds generally imply a further under-prediction of that player’s chances, making her more of a longshot or less of a favourite than she ought to be according to the Wiki Relative Buzz Factor and conditional on the other variables in the model. After including this source of mispricing in the model, the estimated rank distance mispricing remains positive and significant at the 10% level. In this specification, there is a small conditional longshot bias, consistent with the previous literature (Abinzano et al., 2016, 2019; Forrest & Michale, 2007; J., 2014), though here it is not statistically significant. We can also reject the sufficient condition for weak-form market efficiency, $H_0 : \beta_1 = \beta_2 = \beta_3 = 0$ at the 5% level. In column (V), we add tournament fixed effects to the regression model: the estimates and test results are practically the same.\footnote{We checked for misspecification of Eq. (3) using Ramsey RESET tests and did not reject the null hypothesis; the data generating process was not better approximated by including squared terms for any of the regressors.} Table 2 shows results comparable to Table 1 after adding to the estimation samples matches from the 2019 and 2020 (before March) WTA seasons, which we use below for the out-of-sample
Table 1
Model estimates and tests of betting market mispricing for WTA match results, 2015–2018: in-sample period only.

Notes. ***, **, and * indicate significance from zero at 1%, 5%, and 10% levels, respectively, two-sided tests. Standard errors in parentheses were estimated robust to both match- and tournament-level clusters. See Table 1. Each column’s model estimates are equivalent to the respective columns in Table 1, but here matches from the 2019 and 2020 WTA seasons are included in the estimation samples.

forecasting and market efficiency analysis. All of the mispricing test results are robust to extending the sample period in this way.

Heterogeneity in match location and time differences could perhaps be relevant to the impact of the Wikipedia Relative Buzz Factor. To address this, column (I) of Table 3 repeats the model estimates from column (IV) of Table 1, and then columns (II)–(IV) show results after cumulatively dropping from the estimation sample matches in time zones from the east, starting with UTC+11&12 (Sydney/Auckland), then UTC+11&12 (Seoul/Tokyo), and finally UTC+7&8 (Singapore/Hong Kong). The influence of the Wiki Relative Buzz Factor and the rejection of the sufficient condition of weak-form efficiency are robust to dropping these matches from the estimation sample. After dropping matches from all six of the most eastern time zones in the dataset, the mispricing in odds predicted by the buzz factor is greater. This suggests that the Wikipedia profile page views less than 24 h before the start of a match may be less useful in predicting odds mispricing. This would be consistent with the buzz factor being a proxy for crowd judgements on the relative strengths of players’ most recent performances within a tournament. To test whether this could alone explain why the buzz factor can predict bookmaker mispricing, in column (V) of Table 3 we re-estimate the model only for matches in the first round of tournaments. The coefficient on the Wiki Relative Buzz Factor remains marginally significant (\( p \)-value = 0.069) and is larger than when it is estimated over all matches in tournaments. This suggests that the
mismarking is not only driven by whatever happened in the previous round of a tournament, which may have generated interest in a player's Wikipedia profile page. As a further robustness check in this regard, in column (VI) we estimate the model using only first-round matches involving players who had a ranking no greater than 100 and, therefore, were less likely to have come through qualifying rounds in the previous week before entering the main draws of tournaments. In this smaller sample of matches, the coefficient estimate for the Wiki Relative Buzz Factor is even larger than in the previous specifications, but it is also less precisely estimated and thus statistically insignificant at standard levels.

In summary, the results from estimating Eq. (3), and the tests of mismarking by bookmakers, suggest that there might be inefficiencies in the final-result markets of tennis matches. These inefficiencies could be proven by betting on players who are substantially lower-ranked than their opponents or whose Wikipedia profiles show unusually high interest before matches.

3.2 Market inefficiency and the betting strategy

Table 4 shows the results of applying the simple betting strategy described in Section 2.3, by using match outcome probability predictions according to Eq. (4) and applying the Kelly criterion. We estimated the model up to the end of the 2018 season, used this to forecast match outcomes in the 2019 and 2020 seasons, and then applied the Kelly criterion with these forecasts. Column (I) of Table 4 shows the results of the betting strategy for a hypothetical bettor who could place bets at the average pre-match odds offered by the 40–60 bookmakers sampled for each match. The average overround in these markets in 2019 and 2020 (before March) was 5.3%. The out-of-sample probability forecasts and Kelly criterion results suggest betting on 221 of the 5190 considered odds (2595 WTA matches in the period), with a total amount invested equal to 4.3 times the per-bet budget and a return on investment (ROI) of −6.4%, which is no better than the average bookmaker overround.

For curiosity, column (II) of Table 4 presents results whereby the model was estimated and predictions were made using average odds but the best available out-of-sample odds listed on oddsportal.com were used in the Kelly criterion. In this case, a much greater proportion of matches are bet on, the total amount invested over the sample period is 76.6 times the per-bet budget, and the ROI is 3.1%. However, despite the existence of 'odd-checker' websites being available to the bettor, using the best available odds just before a match begins is not normally realistic, due to the transaction costs and time involved with managing a large number of online accounts. Further, there are restrictions that can prevent a bettor from obtaining the best available odds listed on oddsportal.com, such as the location of a bettor affecting which online sportsbooks can be used. This is evidenced by the average overround according to the best available odds being negative in the 2019 and 2020 WTA seasons, suggesting that theoretical arbitrage opportunities were common if not entirely practical.

As a more realistic test of bookmaker inefficiency, column (III) of Table 4 presents results from using the Kelly criterion and the odds from only one online sportsbook. We selected Bet365 because it is the highest-revenue sportsbook in the world and had odds listed on oddsportal.com for almost every WTA match since 2015. From using the model's predictions and the Bet365 odds, we find an out-of-sample ROI of 17.3%, which is generated
from placing bets according to the criterion on 12% of the main draw WTA matches between the beginning of 2019 and March 2020, equivalent to investing 7.15 times the per-bet budget. To check whether these profitable opportunities are driven by the Wiki Relative Buzz Factor, we drop the rank distance measure from the model estimation, with the results shown in column (IV). In this case, fewer matches are bet on and less money is invested according to the Kelly criterion, but the ROI is increased to 28.8% and the absolute return is also greater. To provide a meaningful benchmark ROI using an alternative probability forecasting model of match results, also applied with the Kelly criterion, the same samples of matches, and the Bet365 odds, column (V) of Table 4 shows results using the standard (Elo, 1978) ratings model described in Section 2.3. The ROI from applying the betting strategy with this alternative set of probability forecasts is −12.2%. This model would also have led to substantial amounts of betting activity and absolute losses over the sample period, because of the frequency and magnitude of differences between the simple Elo-predicted probabilities of match outcomes and what bookmaker odds imply, particularly leading to over-betting on longshots. As a further comparison, column (VI) shows betting results using W-Elo, which is a more sophisticated Elo forecasting model of tennis match results that reflects contributions by Kovalchik (2016) and Angelini et al. (2021a). This model gives greater weight to past match wins at prestigious tournaments and takes into account the margins of victory that players achieved. However, the W-Elo model predictions, applied with the Kelly criterion and Bet365 odds, generate a marginally worse ROI and over three times greater absolute losses in our out-of-sample period compared to the standard Elo model in column (V).

Finally, we check whether the betting returns from using the Wiki Relative Buzz Factor are driven by subsets of matches expected to be more or less competitive by bookmakers. We estimate the same model over the 2015–2018 seasons and follow the same betting strategy as in column (IV) of Table 4, which yielded an out-of-sample ROI of 28.8%, except we consider matches in particular odds ranges. The results in Table 5 show that applying the model and betting strategy over matches with intermediate odds, i.e., matches expected to be relatively competitive, generates a marginally higher ROI and a substantially higher absolute return than applying it over all matches, and a substantially higher ROI than applying it over matches expected to be relatively uncompetitive. In this way, the Wiki Relative Buzz factor tends to be a stronger predictor of bookmaker mispricing when matches are expected to be more competitive, and the players involved are by implication more similar in their ability or form.

In summary, a buzz factor about tennis players, constructed from their Wikipedia profile page-view data, provides relevant information that is not being fully incorporated into the match-result prices offered by bookmakers. This information can be used to generate sustained and substantial profits when used in a relatively simple betting strategy.

4. Conclusion

In this paper, we constructed a measure of relative pre-match buzz about tennis players using Wikipedia profile page-view data. We found that this Wikipedia Relative Buzz Factor can predict bookmaker odds-implied forecast errors and the significant mispricing of outcomes, suggesting profitable opportunities for bettors who back players with relatively greater buzz than their opponents going into a match. Using these results to forecast outcome probabilities and the Kelly criterion to select how
much to bet on what matches, we found that tennis result betting markets are inefficient. Prices do not fully incorporate the information contained in the buzz factor. The returns on investment from applying the model and betting strategy were sustained and substantial, including when using only the odds of Bet365, the world’s highest revenue online sportsbook. Two previous studies also found that online information representing the wisdom of crowds can be used to form profitable betting strategies, though with much smaller rates of return than we found in tennis markets (Brown & Reade, 2019; Peeters, 2018). However, it is unclear whether correcting these sources of inefficiency would result in greater profits for bookmakers. What we labelled as mispricing may correlate with unobserved biases and heterogeneity among bettors that bookmakers exploit when setting odds.

There are two natural extensions to this research. The ‘wisdom of crowds’ might explain why a measure constructed from Wikipedia page-view data can predict bookmaker mispricing. While this is an appealing and plausible explanation, we have done nothing here to prove it. This would require complementary data sources that capture explicit predictions about tennis match outcomes or evaluations of the players, like the crowd-sourced football transfer market values used by Peeters (2018). The Wikipedia Relative Buzz Factor may only be capturing relative changes in the media interest in tennis players before matches. If that were the case, then our results could perhaps be described more accurately as being driven by the ‘wisdom of the media’, or by a small number of tennis commentators and pundits who selectively draw attention to some players over others. Second, we can think of no good reason why the betting market inefficiencies found here would be constrained to the top level of women’s professional tennis. It would be interesting for others to check whether these results apply to tennis below the WTA level, men’s tennis, or entirely different sports. To this end, we have provided readily adaptable replication code and instructions for all our results on a GitHub page: https://github.com/philiprami/betting_on_a_buzz.

Notes. Betting strategy results equivalent to column (IV) of Table 4, varying the sample of match odds used in estimating the model and considered for bets by column. Average odds are always used to estimate the models and generate forecasts, but Bet365 odds are used in the Kelly criterion. Column (I): uses only odds in the sample which imply a match win probability of \( p \in (0.0, 0.2) \cup (0.8, 1) \). Column (II): uses only odds in the sample which imply a match win probability of \( p \in (0.4, 0.6) \). Column (III): uses only odds in the sample which imply a match win probability of \( p \in [0.2, 0.8] \). Column (IV): uses only odds in the sample which imply a match win probability of \( p \in [0.4, 0.6] \).
